While the organs affected vary from person to person, most people with TSC have some type of skin irregularities called lesions. Some of the most commonly seen skin lesions are hypomelanotic macules—white or light patches sometimes in an ash-leaf shape and called Ash-leaf spots. Many people in the general population have one or two light areas of skin. However, the presence of three or more such macules in any one individual is considered a major diagnostic finding of TSC. A second major diagnostic feature of the condition is the appearance of small, red bumps called fibromas, either on the face (facial angiofibromas) or around or under the finger- or toenails (ungual fibromas). In addition, rough patches of skin termed shagreen patches are highly specific to a diagnosis of TSC. Finally, groups of small light circles called confetti spots are considered a minor feature of the disorder.

In contrast to skin lesions, brain lesions tend to be serious and are responsible for the neurological symptoms and cognitive impairment seen in severely affected individuals. There are four primary abnormalities that can be detected by magnetic resonance imaging (MRI) or computer tomography (CT) scanning, the first of which are cortical tubers—nodular growths found in the cortex of the brain—and give tuberous sclerosis (literally “hard growths”) its name. Subependymal nodules are growths found underneath the lining of the ventricles in the brain and may cause no problems for the patient unless they grow or begin to block the flow of the cerebral spinal fluid. In contrast, subependymal giant cell astrocytomas, noncancerous brain tumors comprised of star-shaped cells and found in about 5% of patients with TSC, can, if untreated, result in blindness, hydrocephalus (fluid on the brain), and even death. Finally, cerebral white matter migration lines may be seen through radiographic (x-ray) studies and are considered a minor diagnostic feature of TSC.

About 85% of affected individuals will develop epileptic seizures at some point in their lifetime, most beginning by the first year of life. Research suggests that early

control of epilepsy by medication will decrease the chance of a child developing serious mental complications. People with TSC have a range of mental abilities from normal to mild or moderate developmental delays and learning disabilities, to severe intellectual disability. Autism, attention-deficit hyperactivity disorder (ADHD), and other behavioral problems are seen in affected individuals.

Fatty kidney tumors, known as renal angiomyolipomas, are one of the most common findings in TSC patients, affecting 70%–80% of older children and adults, and often cause serious renal malfunction. In addition, the presence of multiple renal cysts (fluid-filled areas within the kidneys) is suggestive of the condition. In addition to these benign growths, malignant kidney tumors may also develop.

The most common cardiac symptom is one or more tumors (cardiac rhabdomyomas) in the heart. These tumors are almost exclusively seen in infants and young children and usually spontaneously disappear by late childhood, thereby avoiding the need for surgery. About 47%–67% of infants and children with TSC have heart tumors and some females develop the rhabdomyomas when they reach puberty.

Tuberous sclerosis complex affects the eyes in the form of retinal nodular hamartomas—multiple growths on the retina. A discoloration on the retina (retinal achromic patch) is also considered a minor feature of the condition.

In addition to the above, symptoms of TSC may include dental pits in the teeth, growths in the rectum (hamartomatous rectal polyps), bone cysts, growths on the gums (gingival fibromas), and other nonspecific growths (nonrenal hamartomas). Women with TSC may develop lymphangiomyomatosis—a serious lung disease. Furthermore, all individuals with TSC are at a higher risk over the general population for developing specific cancers, with 2% of patients developing a malignant tumor in one of the affected body tissues such as kidney or brain.

Diagnosis

When a person exhibits signs of TSC or has a family history of the condition, an evaluation by a medical geneticist, neurologist, or other qualified professional is recommended to confirm (or rule out) the diagnosis and to recommend screening and management options for the individual. In addition, speaking with a genetic counselor may help families understand the genetics behind the disorder, their recurrence risks (chances for having another affected family member), and the practical and

psychosocial implications of the disease on their personal situation.

Detection of hypomelanotic macules (light patches on the skin) can be performed quickly and easily using a special ultraviolet lamp called a Wood's lamp. This light emphasizes the lightened areas on the skin that may otherwise be difficult to see using normal light. Other skin lesions called fibromas are easily visible and identifiable due to their characteristic smooth form, red color, and their even distribution on the face and/or their protrusions among the nails on the fingers and toes. Radiographic imaging using ultrasound, MRI, or CT technology can detect growths present in the brain, kidneys, heart, and eyes.

As basic understanding of and testing methods for tuberous sclerosis complex have improved, criteria used for confirming a diagnosis of tuberous sclerosis complex have been revised. The National Institutes of Health (NIH) held a consensus conference on TSC and published the following diagnostic criteria.

Major features:

- facial angiofibromas or forehead plaque
- nontraumatic ungual or periungual fibroma
- hypomelanotic macules (more than three)
- shagreen patch
- multiple retinal hamartomas
- cortical tuber
- subependymal nodule
- subependymal giant cell astrocytoma
- cardiac rhabdomyoma (one or more)
- lymphangiomyomatosis
- renal angiomyolipoma

Minor features:

- multiple randomly distributed dental pits
- hamartomatous rectal polyps
- bone cysts
- cerebral white matter migration lines
- gingival fibromas
- nonrenal hamartoma
- retinal achromic patch
- confetti skin lesions
- multiple renal cysts

A confirmed diagnosis of TSC requires that a patient display either two major features or one major and two minor features, a suspected diagnosis of one major and one minor feature, and a possible diagnosis of one major or two minor features in any one individual.

KEY TERMS

Bone cysts—Fluid- or air-filled space within the bones.

Cardiac rhabdomyoma—Benign (noncancerous) tumor of the heart muscle.

Cerebral white matter migration lines—Pattern of defects found in the cerebral cortex of the brain probably caused by abnormal migration of neurons during brain formation.

Confetti skin lesions—Numerous light or white spots seen on the skin that resemble confetti.

Cortical tuber—Round (nodular) growth found in the cortex of the brain.

Dental pits—Small, shallow holes or crevices in the tooth enamel.

Facial angiofibromas—Benign (noncancerous) tumors of the face.

Forehead plaque—Flat, fibrous skin growth on the forehead.

Gingival fibromas—Fibrous growths found on the gums.

Hamartomatous rectal polyps—Benign (noncancerous) growths found in the rectum.

Hypomelanotic macules—Patches of skin lighter than the surrounding skin.

Lymphangioomyomatosis—Serious lung disease characterized by the overgrowth of an unusual type

of muscle cell resulting in the blockage of air, blood, and lymph vessels to and from the lungs.

Nonrenal hamartoma—Benign (noncancerous) tumor-like growths not found in the kidneys that often disrupt the normal function of a particular organ system.

Nontraumatic unguinal or periungual fibroma—Fibrous growth that appears around the fingernails and/or toenails.

Renal angiomyolipoma—Benign (noncancerous) tumors in the kidney that are made up of vascular tissue (angio), smooth muscle (myo), and fat (lipoma).

Renal cysts—Fluid or air-filled spaces within the kidneys.

Retinal achromic patch—Defect in the coloration of the retina.

Retinal hamartomas—Benign (noncancerous) tumor found on the retina.

Shagreen patch—Area of tough and dimpled skin.

Subependymal giant cell astrocytoma—Benign (noncancerous) tumor of the brain comprised of star-shaped cells (astrocytes).

Subependymal nodule—Growth found underneath the lining of the ventricles in the brain.

Treatment and management

Optimal treatment for TSC is dependent upon proper disease management. The following should be performed on all patients with TSC at the time of diagnosis to confirm a diagnosis of the disease as well as obtain baseline medical data for future evaluations:

- dermatologic (skin) examination
- fundoscopic (eye) examination
- renal (kidney) imaging study
- cardiac electrocardiogram (ECG) and echocardiogram (ECHO)
- brain magnetic resonance imaging (MRI)

Since the characteristic feature of tuberous sclerosis complex is the growth of benign tumors, treatments are often focused on appropriate surgical interventions to arrest tumor growth or remove tumors whose growth has resulted in or may lead to medical complications, especially in the kidney or brain. Regular brain MRI

studies should be performed in children and adults with previous findings as clinically indicated and every one to three years in children and, less frequently, in adults without symptoms. In addition, periodic brain electroencephalogram (EEG) studies are recommended for both children and adult patients when clinically indicated.

Children without previous kidney findings should be offered renal imaging studies using ultrasound, MRI, or CT scanning every three years until they reach adolescence and then, every one to three years as adults. Likewise, asymptomatic adults should have imaging of their kidneys done every one to three years. Both children and adults who have kidney symptoms should be monitored using imaging studies every six months to one year until the tumor growth stabilizes or decreases.

Any child with cardiac rhabdomyomas should be monitored every six months to one year until the tumor stabilizes or regresses completely. Adults with previous findings of cardiac tumors should be monitored as clinically recommended by their treating physician. While

QUESTIONS TO ASK YOUR DOCTOR

- How often should brain and MRI studies be performed?
- What are the risks and benefits of vigabatrin therapy?
- How early should we begin physical and occupational therapies?
- What developmental milestones should I look for in my child?

monitoring is important, cardiac rhabdomyomas, as well as retinal lesions and gingival fibromas, usually do not require treatment. In contrast to these benign tumors, cancerous tumors that develop in patients with TSC should be treated by an oncologist as appropriate.

Facial angiofibromas and peri- and subungual fibromas on the nails are common symptoms in TSC patients. While they are generally not medically significant, they can cause skin irritations or be a cosmetic concern to the individual. Special techniques involving dermabrasion or laser therapy can be performed by a dermatologist or plastic surgeon to remove such growths.

Patients with seizure disorders are prescribed specific medications to control seizures. The antiepileptic drug vigabatrin has been shown to be an effective medication in infants with seizures and has been shown to improve long-term outcomes in behavioral and intellectual areas. In addition to controlling seizures, early intervention programs that include special education, behavior modification, physical and occupational therapies, and speech therapy is often recommended for individuals with learning disabilities, developmental delays, intellectual disability, autism, and other mental and emotional disorders.

Neurodevelopmental testing is appropriate at the time of diagnosis for all children and should be performed every three years until adolescence and for any adult diagnosed with TSC who displays signs of impairment. Subsequent evaluations should be done on both children and adults with previous findings of developmental delays or problems.

While present in only 1% of patients with TSC, almost exclusively in females, lung complications can be serious and even fatal. Symptoms may include spontaneous pneumothorax (air in the chest cavity), dyspnea (difficult breathing), cough, hemoptysis (spitting of blood), and pulmonary failure. Therefore, a computed

tomography (CT) scan of the lungs is recommended for any TSC patient who has symptoms of lung disease or complications and for all female TSC patients at the age of 18. Clinical trials involving Tamoxifen and progesterone treatments have shown positive results in some patients with lung disease.

Prognosis

The lifespan of individuals with TSC varies with the severity of the condition in any one person. Many affected people have normal life expectancies and a high quality of life, relatively free of symptoms or complications of the disease. Conversely, severely affected or disabled individuals may experience a shortened lifespan and a high rate of illness and medical complications. Therefore, proper disease management, diagnostic monitoring, and follow-up are critical to achieving and maintaining optimal health in patients with TSC.

Turner syndrome

Definition

Turner syndrome is a chromosomal disorder affecting females wherein one of the two X chromosomes is defective or completely absent.

Description

Chromosomes are structures in the nucleus of every cell in the human body. Chromosomes contain the genetic information necessary to direct the growth and normal functioning of all cells and systems of the body. A normal individual has a total of 46 chromosomes in each cell, two of which are responsible for determining gender. Normally, females have two X chromosomes and males have one X and one Y chromosome.

In Turner syndrome, an error occurring very early in development results in an abnormal number and arrangement of chromosomes. Most commonly, an individual with Turner syndrome will be born with 45 chromosomes in each cell rather than 46. The missing chromosome is an X chromosome. The affected person is always female.

Genetic profile

Turner syndrome is a disorder associated with characteristic defects in the X chromosome. The most common presentation is a female with a single X chromosome and an absent X chromosome. A Greek

Human karyotype of Turner syndrome. (Alila Medical Media/Shutterstock)

KEY TERMS

Chromosome—A microscopic thread-like structure found within each cell of the body that consists of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Changes in either the total number of chromosomes or their shape and size (structure) may lead to physical or mental abnormalities.

Mosaic—A term referring to a genetic situation in which an individual's cells do not have the exact same composition of chromosomes. In Down syndrome, this may mean that some of the individual's cells have a normal 46 chromosomes, while other cells have an abnormal 47 chromosomes.

Ovary—The female reproductive organ that produces the reproductive cell (ovum) and female hormones.

Zygote—The cell formed by the uniting of egg and sperm.

study from 1999 reported that the intact X chromosome was as likely to come from the mother as from the father. This means that there is no parental pattern of responsibility for the missing or defective X chromosome.

Another less common genetic pattern for Turner syndrome (35%) is a mosaic. A Danish study reported that mosaicism has an effect on malformations that are associated with Turner syndrome. Research reported in 1997 noted that the karyotype can have a significant effect on the growth of children with Turner syndrome.

The exact location of the genes on the X chromosome involved in Turner syndrome has not been determined. As of 2015, evidence indicated that there is a locus for stature on the distal portion of the short arm, there are loci for normal ovarian function on both the short and long arms, and there are loci contributing to fetal viability on the long arm of X.

Demographics

The prevalence of Turner syndrome is widely reported as being approximately 1 per 2,000 live female births, although researchers have reported prevalence rates that range from 1 in 3,125 to 1 in 5,000 live female births.

About 1%–2% of all female conceptions have a missing X chromosome. Of these, the majority (99%) spontaneously abort, usually during the first trimester of pregnancy. With ultrasound being used more frequently,

researchers have realized that some pregnancies with a missing X chromosome that progress into the second trimester are associated with nuchal cysts, severe lymphedema, or hydrops fetalis. These pregnancies are associated with a high frequency of fetal death.

Signs and symptoms

Turner syndrome is characterized by delayed growth that leads to a small stature and frequent infertility. Individuals with Turner syndrome report an increased incidence of fractures in childhood and osteoporotic fractures in adulthood. The incidence of diabetes mellitus (both insulin dependent and non-insulin-dependent varieties) has been reported to be increased in Turner syndrome. Ischemic heart disease, stroke, and hypertension are also more common.

Growth in children with Turner syndrome is characterized by a slight intrauterine growth retardation, relatively normal growth rates for the first several years of life, a progressive deceleration of growth later in childhood, and the lack of a pubertal growth spurt. Growth patterns of Chinese girls with Turner syndrome parallel those of Caucasians, although their ultimate height is still less than normal.

Contrary to earlier reports, most individuals with Turner syndrome are not intellectually disabled. They may have some learning disabilities, particularly with regard to spatial perception, visual-motor coordination, and mathematics. As a result, the nonverbal IQ in Turner syndrome tends to be lower than the verbal IQ. Cardiovascular malformations are well-recognized congenital anomalies in Turner syndrome. Dilation and dissection of the aorta are reported in approximately half of women with Turner syndrome. Because of the potential consequences of aortic dilation, some experts recommend screening all individuals with Turner syndrome. However, the specific timing for this screening remains controversial.

Juvenile arthritis, an autoimmune condition, has been recently associated with Turner syndrome. The prevalence seems to be at least six times greater than would be expected if the two conditions were only randomly associated. Women with Turner syndrome have an elevated prevalence rate of dental caries and other periodontal conditions such as gum disease and plaque.

Normal pubertal development and spontaneous menstrual periods do not occur in the majority of children with Turner syndrome. It is estimated that 3%–8% of girls with a single X chromosome and 12%–21% of females with sex chromosome mosaicism may have normal pubertal development and spontaneous menstrual periods. A few pregnancies have been reported in women with Turner syndrome.

QUESTIONS TO ASK YOUR DOCTOR

- When should screening for aortic dissection take place?
- When should we consider plastic surgery?
- Should we test for other associated problems, such as heart or kidney disorders?
- Is a hearing test recommended?

Diagnosis

Turner syndrome is diagnosed on the basis of genetic analysis of chromosomes. This can be done prior to birth. However, the predictive value of amniocentesis in diagnosing Turner syndrome varies from 21%–67%. There is no significant relation between mother's age and risk of Turner syndrome.

Treatment and management

Because it is so dangerous, experts suggest screening for aortic dissection, although the specific timing for this screening is controversial. Plastic surgery to correct webbing of the neck should be considered at an early age (before entering school) for girls with Turner syndrome.

Most individuals with Turner syndrome require female hormone therapy to promote development of secondary sexual characteristics and menstruation. The time of beginning therapy varies with individuals. Experts recommend that therapy begin when a woman expresses concern about her onset of puberty.

All women receiving long-term, exogenous female hormone therapy require periodic gynecological examinations because those with Turner syndrome have an increased risk of developing neoplasms such as gonadoblastoma and dysgerminoma, which arise from their rudimentary streak gonads.

Prognosis

Most women with Turner syndrome can live relatively normal lives. The prognosis for people with Turner syndrome is dependent on other conditions that may be present. Care must be taken to regularly monitor them for the health problems that are associated with Turner syndrome. For example, heart or kidney defects, hearing loss, or the development of inflammatory bowel disease may significantly impact the quality of life. Without these types of conditions, however, their life

expectancy is normal. Support will be necessary to help an adolescent girl cope with body image issues and to help some women accept the fact that they will never be able to have children.

Twin reversed arterial perfusion (TRAP) sequence

Definition

Twin reversed arterial perfusion (TRAP) sequence, also called acardia, is a very rare and serious condition that occurs exclusively in monochorionic pregnancies (identical twins that share a placenta). The condition occurs when one twin, the "acardiac" twin, lacks a functioning heart and receives blood circulated by the normally developing "pump" twin. The pump twin is at risk for cardiac failure because of the heavy demand placed on its heart.

Description

TRAP sequence is a pregnancy complication in which twins abnormally share blood flow from the umbilical artery of one twin to the umbilical vein of the other. This abnormal connection can cause serious complications including loss of the pregnancy. In TRAP sequence pregnancies, there may be a fused placenta or abnormal connection between the twins in the placenta. The placenta is the important interface of blood vessels between a mother and baby through which babies receive nutrients and oxygen. This abnormal connection forces the twin with stronger blood flow to pump blood for both. This strains the heart of the pump twin. This abnormal connection causes the malformed twin to receive blood directly from the pump twin before this blood gathers new oxygen. The poorly oxygenated blood from the pump twin may be the cause of the other malformations in the acardiac twin. The abnormal blood flow between twins is the most likely cause for the variety of malformations and complications of this condition.

The acardiac twin

The acardiac twin is severely malformed and may be incorrectly referred to as a tumor. In 1902, a physician named Das established four categories of acardiac twins based on their physical appearance. There is controversy surrounding the use of these traditional four categories because some cases are complex and do not fit neatly into one of Das's four categories. These four traditional categories include acardius acephalus, amorphus, aniceps, and acornus:

- Acardius acephalus is the most common type of acardiac twin, being found in 60%–75% of cases. These twins do not develop a head, but may have an underdeveloped skull base. They have legs, but do not have arms. On autopsy, they are generally found to lack chest and upper abdominal organs.

- **Acardius amorphus** occurs in 20% of cases and appears as a disorganized mass of tissues containing skin, bone, cartilage, muscle, fat, and blood vessels. This type of acardiac twin is not recognizable as a human fetus and contains no recognizable human organs.
- **Acardius aniceps** is the most developed form of acardiac twin. This form has arms, legs, and a partially developed head with brain tissues and facial structures. This type of acardiac twin is associated with a high risk for complications in the normal twin.
- **Acardius acornus** is the rarest type of acardiac twin. This type of acardiac twin presents as an isolated head with no body development.

Thus, the acardiac twin can have various and numerous malformations.

The pump twin

The pump twin can develop complications as a result of the increased work of providing blood flow to the acardiac twin. The pump twin may develop cardiac failure or overload, leading to fetal death. About 10% of pump twins also have a malformation.

Pregnancy complications

Polyhydramnios, or extra amniotic fluid, is a frequent complication of this condition. The extra fluid can cause early rupture of the amniotic membranes and premature delivery. It is also possible to have a miscarriage of the whole pregnancy, either due to polyhydramnios and premature delivery, or due to complications from *in utero* fetal demise of the acardiac twin. This latter condition can lead to the demise of the pump twin due to the abnormal blood flow between the two.

Genetic profile

There is no single known genetic cause for TRAP sequence and the condition does not appear to run in families. There have been a number of types of chromosomal conditions reported in both the acardiac and the pump twin. However, the chromosome abnormality is not believed to be the underlying cause of the condition, but rather the abnormal blood flow between the twins. About 9% of pump twins have a chromosomal abnormality. In most cases, the pump twin is genetically identical to the acardiac twin and they both have normal chromosomes. Specific rates for recurrence are unknown. However, a mother who has had a pregnancy complicated by TRAP sequence is very unlikely to have another pregnancy with the same complication.

KEY TERMS

Dizygotic—From two zygotes, as in nonidentical, or fraternal, twins. The zygote is the first cell formed by the union of sperm and egg.

Fetal echocardiogram—A detailed ultrasound of the fetal heart usually performed between 18 and 24 weeks of gestation.

Fetoscope—A tubular instrument that can be inserted into the abdomen and uterus and used to visualize a fetus during pregnancy.

Fetus—The term used to describe a developing human infant from approximately the third month of pregnancy until delivery. The term “embryo” is used prior to the third month.

Monozygotic—From one zygote, as in identical twins. The zygote is the first cell formed by the union of sperm and egg.

Placenta—An organ in the uterus during pregnancy that allows nutrients and oxygenated blood to flow between mother and fetus.

Polyhydramnios—An overabundance of amniotic fluid present in the amniotic sac surrounding a fetus that can lead to early labor and delivery.

Demographics

TRAP sequence is a rare complication of twinning, occurring only once in about every 35,000 identical twin births. TRAP sequence is believed to complicate 1% of monozygotic twin pregnancies. Risks in triplet, quadruplet, and other higher-order pregnancies are even higher. However, it is believed the condition is underreported because some women miscarry before the condition is identified. Some studies have suggested a slightly higher number of female fetuses with the condition, but other studies have not borne this out. This condition has been documented for more than five centuries and it occurs in many countries and among different races. This condition does not appear to be associated with maternal or paternal age. Chronic illnesses like seizures or lifestyle choices like smoking in the mother do not seem to be contributing factors.

Diagnosis

A mother carrying an acardiac twin pregnancy is not likely to have any unusual symptoms. TRAP sequence is most often found incidentally on prenatal ultrasound. No two cases of acardiac twins are formed exactly alike, so

they may present differently. During ultrasound, an acardiac twin may appear as tissue mass or it may appear to be a twin who has died in the womb. TRAP sequence is always suspected when, on ultrasound, a twin once considered to be dead shows signs of life. The acardiac twin may begin to move or grow or there may be visible blood flow through that twin's umbilical cord. In 50% of cases the acardiac twin has only two, instead of the normal three, vessels in the umbilical cord. A two-vessel umbilical cord may also be found in some normal pregnancies.

Ultrasound diagnostic criteria for the acardiac twin usually include:

- absence of fetal activity
- no heartbeat
- continued growth
- increasing soft tissue mass
- undergrowth of the upper torso
- normal growth of the lower trunk

TRAP sequence may also be missed on prenatal ultrasound. A 1991 report describes an acardiac twin who was missed on ultrasound and only detected at delivery. In rare cases, a diagnosis of acardia is not possible until autopsy.

Treatment and management

There is no consensus on which therapy is best for pregnancies complicated by TRAP sequence. No treatment can save the acardiac twin, so the goal of prenatal therapy is to help the pump twin. The pump twin is not always saved by prenatal treatment.

Cutting off blood circulation to the acardiac twin has been attempted and accomplished through a variety of techniques. The most common techniques are cauterization, which uses heat to seal off the blood-vessel connections between the twins, and radio-frequency ablation (RFA), which accomplishes the same thing but with a smaller instrument and a lower risk of complications. These are both outpatient procedures that can be performed by inserting small hollow needles called trochars through the mother's abdomen into the amniotic sac. Instruments such as a fetoscope (to visualize the fetuses) and coagulation devices are inserted through the trochars. Medications like digoxin may be used to treat congestive heart failure in the pump twin.

Fetal echocardiography is recommended to assist with early detection of heart failure in the pump twin. Chromosome studies are recommended for both fetuses in all pregnancies complicated by TRAP sequence. If an

QUESTIONS TO ASK YOUR DOCTOR

- What type of therapy can lower the risk for heart failure and premature birth of the normal pump twin?
- How often are prenatal ultrasounds recommended?
- What are the risks to the pump twin associated with interrupting the blood flow to the acardiac twin?
- What are my chances of this occurring in future pregnancies?

early delivery of the pump twin is likely, then treatment of the fetus with steroids is recommended to mature the fetal lungs. Delivery at a major medical center with a neonatologist present for the delivery is also recommended. The neonatologist can be prepared to treat the surviving infant for any complications.

Prognosis

The acardiac or parasitic twin never survives, given the severe malformation and lack of a functioning heart. Complications associated with having an acardiac twin cause 50%–75% of pump twins to die. The risk to the pump twin increases with the weight of the acardiac twin. If the acardiac twin outweighs the pump twin by 50%, there is a 65% mortality rate for the pump twin. If the acardiac twin outweighs the pump twin by 75%, then the pump twin dies in 95% of cases. The pump twin is at risk for heart failure and complications associated with premature birth. Heart failure in the pump twin is common. The pump twin of an acardiac twin pregnancy has about a 10% risk for malformations. However, treatment with cord coagulation or radio frequency ablation increases survival in the normal twin up to 90%. A risk with these procedures is premature delivery, although the average gestational age at delivery is 36 to 38 weeks. There is uncertainty about when to treat the pregnancy and when to watch and wait. Some researchers suggest that treatment should occur only if heart failure in the pump twin is imminent. Others recommend earlier treatment. The argument follows that because prognostic indicators for the pump twin are lacking, assistance for the pump twin should begin as soon as possible. There is no long-term data available on the outcomes of surviving pump twins.

Urea cycle disorders

Definition

Urea cycle disorders are inborn errors in metabolism that can lead to brain damage and death. They involve a deficiency in one of the enzymes required by the urea cycle, which removes ammonia from the blood.

Description

Ammonia accumulates in toxic levels if the urea cycle does not convert nitrogen from protein metabolism into urea for excretion into the urine. A series of biochemical reactions are necessary to complete the urea cycle. The urea cycle takes place in liver cells. When an enzyme is missing or deficient, the cycle is interrupted and nitrogen accumulates in the form of ammonia. It cannot be excreted from the body and enters the bloodstream, damaging nervous tissues, including the brain.

Seizures, poor muscle tone, respiratory distress, and coma follow if an affected infant is not treated. Acute neonatal symptoms are most frequently seen in boys with ornithine transcarbamylase (OTC) deficiency. Intellectual disability and even death may follow. People with partial deficiencies may not discover the problem until childhood or adulthood. Children may avoid meat or other protein foods. As ammonia levels rise in the body, individuals begin to show lethargy and delirium. Left untreated, they may suffer a coma or death.

Sometimes young people with urea cycle disorders who go undiagnosed begin to show behavioral and eating problems. Those with partial enzyme deficiencies may experience episodes of high ammonia levels in the blood. This can occur after suffering from viral illnesses, including chicken pox; after eating high-protein meals; or even after significant physical exertion.

The incidence of adults with urea cycle disorders is increasing. Recent evidence has indicated that some people have survived undiagnosed into adulthood. They can

KEY TERMS

Encephalopathy—The medical term for any global dysfunction of the brain. It is not a single disease but rather a syndrome that has many different causes and prognoses.

Enzyme—A protein that catalyzes a biochemical reaction or change without changing its own structure or function.

Urea cycle—A series of complex biochemical reactions that remove nitrogen from the blood so ammonia does not accumulate.

suffer stroke-like symptoms, lethargy, and delirium. Without proper diagnosis and treatment, adults are at risk for permanent brain damage, coma, and death. Symptoms can appear after giving birth or after contracting a virus, and some adults have shown deficiencies after using the medication valproic acid (an antiepileptic drug). Adult onset is more common in women with OTC deficiency.

Different enzymes may be lacking in the various forms of urea cycle disorders. The six major disorders of the urea cycle include the following:

- CPS—Carbamoyl phosphate synthetase
- NAGS—N-acetylglutamate synthetase
- OTC—Ornithine transcarbamylase
- ASD—Argininosuccinic acid synthetase (citrullinemia)
- ALD—Argininosuccinase acid lyase (argininosuccinic aciduria)
- AG—Arginase

Genetic profile

Urea cycle disorders, except for OTC deficiency, are inherited as autosomal recessive traits. OTC deficiency is inherited as an X-linked trait from the mother.

The six major disorders of the urea cycle are caused by mutations of different genes.

- CPS is due to a mutation in the *CPS1* gene located on the long arm of chromosome 2 and responsible for coding the enzyme carbamoyl phosphate synthetase I, which is necessary for many steps in the urea cycle.
- NAGS is due to a mutation in the *NAGS* gene located on the long arm of chromosome 17 and responsible for the enzyme N-acetylglutamate synthase utilized in the urea cycle.
- ASD, also known as citrullinemia, is due to a mutation in genes *ASS1* and *SLC25A13*.
- ALD is due to a mutation in the *ASL* gene located on the long arm of chromosome 7 and responsible for coding the enzyme argininosuccinic aciduria, which is necessary to start reactions within the urea cycle.
- AG is due to a mutation in the *ARG1* gene located on the long arm of chromosome 6 and responsible for the enzyme arginase, which controls the last step of the urea cycle.

If any of these genes are mutated, the urea cycle will be disrupted, and a urea cycle disorder will result.

Demographics

It is estimated that the incidence of urea cycle disorders is about 1 in 30,000 births. These disorders affect males and females equally, except for OTC deficiency, which is more prevalent in males because it is an X-linked disorder.

Signs and symptoms

In severe urea cycle disorders, rising ammonia levels cause irritability, vomiting, and lethargy within the first 24–72 hours of life. Seizures, poor muscle tone, respiratory distress, and coma follow if the infant is not treated. Acute neonatal symptoms are most frequently seen in boys with ornithine transcarbamylase or OTC deficiency. However, patients with mild or moderate urea cycle enzyme deficiencies may not show symptoms until early childhood. In childhood, early symptoms include failure to thrive, inconsolable crying, agitated and/or hyperactive behavior, and refusal to eat. Later symptoms include vomiting, lethargy, delirium, coma, and eventually death if left untreated. Specifically for a deficiency in arginase, childhood symptoms are progressive, usually between the ages of one and four, and include failure to thrive, spastic tetraplegia, seizures, and abnormal movements.

QUESTIONS TO ASK YOUR DOCTOR

- What specific dietary recommendations do you have?
- Can you recommend a dietitian?
- How often should blood tests be performed?
- What symptoms should I report immediately?

Diagnosis

Early detection through blood testing is essential to prevent irreversible brain damage in severe cases of urea cycle disorders. An increase in blood ammonium levels is the primary indicator of a urea cycle disorder, followed by central nervous system manifestation such as irritability progressing to lethargy, decrease in body temperature, seizures, altered muscle tone, and encephalopathy.

Treatment and management

Therapy consists of eating a diet that provides enough protein so the body gets the essential amino acids needed for growth, but not so much that toxic levels of ammonia are formed. Treatment may entail a protein-restricted diet together with medications that provide alternative pathways for the removal of ammonia from the blood. These medications tend to be unpalatable and may be given by way of tube feedings. Blood tests are needed to monitor levels of ammonia, and hospitalizations may become necessary if levels rise too high. Liver transplant may also be a potential treatment protocol, and studies have shown that it has had success in some cases.

Prognosis

With early detection and proper diet restrictions, individuals can lead relatively normal lives. However, irreversible brain damage can develop quickly in severe cases that go undetected.

Urogenital adysplasia syndrome

Definition

Urogenital adysplasia syndrome describes a rare disorder characterized by anomalies of the kidneys, urinary tract, and/or reproductive system.

Description

The identification of urogenital adysplasia syndrome resulted from the combined work of multiple physicians examining several families. The first report of siblings born with both kidneys missing (bilateral renal agenesis) was made by H. Madisson in 1934. However, the term “hereditary renal adysplasia” was not coined until 1973 when R. M. Buchta combined the terms “aplasia,” the complete absence of one or both kidneys, and “dysplasia,” developmental anomalies of the kidneys, to form the term “adysplasia” to apply to familial, bilateral kidney anomalies. In 1980, R. N. Schimke and C. R. King suggested that the developmental defects in certain families’ reproductive and urinary tracts (mesonephric and müllerian ducts) may have a common genetic basis and that the designation “hereditary urogenital adysplasia” should be used as a descriptive syndrome name.

Urogenital adysplasia syndrome is an autosomal dominant inherited condition. The symptoms of urogenital adysplasia syndrome are variable. Affected individuals within families may have features of the disease that include one or two missing kidneys (renal agenesis), one or two malformed kidneys (renal dysplasia), bladder anomalies, ureter abnormalities, hypertension, vaginal anomalies, uterine anomalies, fallopian tube anomalies,

lack of a menstrual period (amenorrhea), and cysts of the seminal vesicle. Fetuses that have two missing or very abnormal kidneys are often born with a condition called Potter’s sequence, or syndrome. Potter’s sequence occurs when the fetal kidneys cannot produce enough amniotic fluid to surround the fetus as it develops. Features of Potter’s sequence include wide-set eyes, squashed nose, small and receding chin, low-set ears, deformities of the hands and feet, and incompletely formed lungs (lung hypoplasia).

Urogenital adysplasia syndrome is also referred to as renal hypodysplasia/aplasia 1 (RHDA1), renal agenesis, and renal hypoplasia, isolated. The age of diagnosis for affected individuals often is determined by the symptoms they exhibit. Individuals affected by urogenital adysplasia syndrome may be diagnosed prenatally based on two (bilateral) missing kidneys, at birth based on the features of Potter’s syndrome, or not until adulthood with the findings of reproductive problems or one missing kidney.

Genetic profile

The genetic causes of urogenital adysplasia syndrome are complex and related to mutations in three or more different genes. As of 2015, renal hypodysplasia/aplasia 1 was thought to be caused by mutations in the *ITGA8* gene found on chromosome 10p13. Renal agenesis is believed to be caused by mutations in the *RET* gene found on chromosome 10q11.21, and renal hypoplasia, isolated, is believed to be caused by mutations in the *PAX2* gene found on chromosome 10q24.31.

All three types of urogenital adysplasia are inherited in an autosomal recessive manner. In an autosomal recessive disorder, the individual affected with the condition inherits a mutation from both parents. The parents are carriers of the disease but are not affected. Parents who carry a mutation for the same disease have a 25%, or 1 in 4, chance to have an affected child with each pregnancy.

There is also a form of urogenital adysplasia syndrome known as Mayer-Rokitansky-Küster-Hauser syndrome, which is inherited in an autosomal dominant manner. In an autosomal dominant condition, only one mutated copy of a gene is necessary for a person to experience symptoms of the condition. If a parent has an autosomal dominant condition, there is a 50% chance for each of his or her children to have the same or a similar condition. The genetic cause for this condition was not known as of 2015.

Demographics

Urogenital adysplasia syndrome is a genetic condition that has been found in individuals descended from a

KEY TERMS

Adysplasia—A term referring to the combination of renal agenesis (complete absence of one or both kidneys) and renal dysplasia (developmental anomaly of the kidney).

Amniotic fluid—Fluid contained in a sac within the uterus that surrounds and protects the fetus during its development.

Mesonephric duct—Embryonic structure that in the male becomes the vas deferens, and in both sexes gives rise to the ureters leading to the kidney.

Müllerian ducts—Two embryo structures that in the female develop into vagina, uterus, and oviducts, and in the male disappear except for the vestigial vagina masculina and the appendix testis.

Oligohydramnios—Reduced amount of amniotic fluid. Causes include nonfunctioning kidneys and premature rupture of membranes. Without amniotic fluid to breathe, a baby will have underdeveloped and immature lungs.

Renal agenesis—Complete absence of one or both kidneys.

Renal dysplasia—A developmental anomaly of the kidney.

variety of ethnic backgrounds. Although the exact frequency of urogenital adysplasia syndrome is unknown, it can be estimated based on past family studies. Family studies also indicate that disease symptoms are more severe in males than in females. Between 1 in 3,000 and 1 in 10,000 newborns are born with two severely malformed or missing kidneys (bilateral renal agenesis or dysplasia). It is suggested that urogenital adysplasia syndrome is currently underdiagnosed due to its variability of symptoms within families.

Signs and symptoms

The signs and symptoms of urogenital adysplasia syndrome vary from individual to individual (variable expressivity). Most people diagnosed with urogenital adysplasia syndrome have anomalies in their urinary and reproductive tract. The most common findings include missing kidneys and uterine abnormalities. Specific features may include any of the following:

- one or two missing kidneys (renal agenesis)
- one or two malformed kidneys (dysplastic kidneys)
- bladder anomalies

- hypertension
- vaginal anomalies
- uterine anomalies
- fallopian tube anomalies
- lack of a menstrual period (amenorrhea)
- cysts of the seminal vesicle
- heart anomalies
- small, underdeveloped chin
- intestinal abnormalities
- other facial abnormalities

Additionally, since Potter's sequence occurs when the fetal kidneys cannot produce enough amniotic fluid to cushion the fetus as it develops, the features of Potter's sequence can suggest a diagnosis of urogenital adysplasia syndrome in a baby with wide-set eyes, squashed nose, small and receding chin, low-set ears, deformities of the hand and feet, and incompletely formed lungs (lung hypoplasia).

Diagnosis

Diagnosis of urogenital adysplasia syndrome is usually made by physical examination by a medical geneticist or other physician, an ultrasound of the kidneys and the urinary and reproductive tracts, and a detailed medical family history.

Prenatal diagnosis of severe cases can sometimes be made using targeted ultrasound imaging during pregnancy to provide pictures of the fetal kidneys, bladder, and amniotic fluid levels. Ultrasound results that may indicate urogenital adysplasia syndrome include low amniotic fluid levels (oligohydramnios) combined with missing or abnormally formed kidneys (renal agenesis or adysplasia). Ultrasonographic screening for parents and siblings of infants born with agenesis or adysplasia of the kidneys is recommended, since the diagnosis of urogenital adysplasia syndrome can have implications for their health and medical care.

Treatment and management

Urogenital adysplasia syndrome is a genetic condition that has no specific treatment that can remove, cure, or fix its underlying genetic error. Treatment for urogenital adysplasia syndrome is limited to the management of specific symptoms. Individuals with only one kidney should be followed by a nephrologist who can evaluate their need for antihypertensive agents and/or a kidney transplant. Individuals affected by urinary tract anomalies should be followed by an urologist. Individuals with reproductive anomalies can consult an obstetrician/gynecologist who specializes in pelvic reproductive reconstructive surgery for infertility, endometriosis, pelvic pain, and congenital anomalies. Medical geneticists and

QUESTIONS TO ASK YOUR DOCTOR

- What form of urogenital adysplasia syndrome does my child have?
- Is genetic testing available for this condition?
- What are the chances of having another child affected with urogenital adysplasia syndrome?
- Which medical specialist does my child need to see?
- Can you recommend any literature or websites to learn more about this condition?

genetic counselors are available to discuss inheritance patterns of the syndrome and reproductive options with affected individuals. Pregnant women whose fetuses are at risk for urogenital adysplasia syndrome should be evaluated by a perinatologist or maternal fetal medicine specialist. Other specialists and/or surgeons may be added to an individual's medical team to address specific individual concerns.

Prognosis

Since urogenital adysplasia syndrome results in a variety of different physical symptoms, the prognosis for each affected individual is very different.

Individuals who have one normal kidney and one malformed kidney have an excellent prognosis, and most live normal lives. Individuals who have only one functional kidney may have issues with hypertension and proteinuria.

Individuals with reproductive anomalies may be infertile or have fertility issues. An obstetrician/gynecologist who specializes in pelvic reproductive reconstructive surgery for infertility, endometriosis, pelvic pain, and congenital anomalies may be able, in some cases, to correct some anomalies and restore fertility.

On the most severe end of the spectrum, babies found prenatally to have low amniotic fluid (oligohydramnios) and two missing kidneys (bilateral agenesis or adysplasia) might be miscarried, stillborn, or die after birth due to combined health implications of incompletely formed lungs and missing kidneys.

Usher syndrome

Definition

Usher syndrome is an inherited condition that causes hearing loss and a form of vision loss called retinitis pigmentosa (RP), which worsens over time. Some people with Usher syndrome also have difficulties with balance and/or psychological problems. Although the symptoms of Usher syndrome were first described in 1858 by an ophthalmologist named Albrecht von Graefe, it was not until 1914 that it was well documented and recognized to be a genetic condition by another ophthalmologist, Charles Usher. There are three forms of Usher syndrome: type I, II, and III. Genetic research has shown there are many genes located on different chromosomes, all of which can lead to one of the types of Usher syndrome if they are altered.

Description

Usher syndrome is sometimes called hereditary deafness—retinitis pigmentosa, or retinitis pigmentosa and congenital deafness. Usher syndrome causes a specific type of hearing impairment called sensorineural

Colored scanning electron micrograph of human chromosome 10. Gene defects on this chromosome are related to diseases such as Usher syndrome, nonsyndromic deafness, and a form of porphyria. (SPL/Science Source)

hearing loss (SNHL). In order to understand how SNHL occurs, it is important to first understand how normal hearing works. The ear can be divided into three main parts: the outer ear, the middle ear, and the inner ear. The parts of the outer ear include the pinna (the visible portion of the ear), the ear canal, and eardrum. The pinna directs sound waves from the environment through the ear canal and toward the eardrum. The eardrum vibrates and causes tiny bones called ossicles located in the middle ear to move. This movement causes pressure changes in fluids surrounding the parts that make up the inner ear. The main structures of the inner ear are the cochlea and the vestibular system. These structures send information regarding hearing and balance to the brain. The cochlea is shaped like a snail shell and it contains specialized sensory cells (hair cells) that change the sound waves into electrical messages. These messages are then sent to the brain through the auditory nerve that allows the brain to

“hear” sounds from the environment. The vestibular system is a specialized organ that helps people maintain their balance. The vestibular system contains three structures called semicircular canals, which send electrical messages to the brain about movement and body position. This allows people to maintain their balance when moving by sensing changes in their direction and speed.

Sensorineural hearing loss occurs when parts of the inner ear (including the cochlea and/or auditory nerve) do not work correctly. The amount or degree of hearing loss can be described by measuring the hearing threshold (the sound level that a person can just barely hear) in decibels (dB). The greater a person’s dB hearing level, the louder the sound must be to just barely be heard. Hearing loss is often defined as mild, moderate, severe, or profound. For people with mild hearing loss (26–45 dB), understanding conversations in a noisy environment, at a distance, or with a soft-spoken person is difficult. Moderate hearing loss (46–65 dB) causes people to have difficulty understanding conversations, even if the environment is quiet. People with severe hearing loss (66–85 dB) have difficulty hearing conversation unless the speaker is nearby or is talking loudly. Profound hearing loss (85 dB) may prevent people from hearing sounds from their environment or even loud conversation. People with Usher syndrome generally have moderate, severe, or profound SNHL, depending upon the type with which they are diagnosed.

Usher syndrome also causes a specific type of vision loss called retinitis pigmentosa (RP). The eye is made up of many different types of cells and tissues that all work together to send images from the environment to the brain, similar to the way a camera records images. When light enters the eye it passes through the lens and lands on the retina, a very thin tissue lining the inside of the eye. The retina is actually made up of ten different layers of specialized cells, which allow the retina to function similarly to film in a camera, by recording images. There is a small, yellow-pigmented area called the macula, located in the back of the eye in the center of the retina. The retina contains many specialized cells called photoreceptors, which sense light coming into the eye and convert it into electrical messages that are then sent to the brain through the optic nerve. This allows the brain to “see” the environment.

The retina contains two types of photoreceptor cells: rod cells and cone cells. Rod cells are located primarily outside of the macula and they allow for peripheral (side) and night vision. Most of the photoreceptor cells inside of the macula are the cone cells, which are responsible for perceiving color and for viewing objects directly in front of the eye (central vision). In RP, the rod and cone cells degenerate (breakdown) and die over time, resulting in

night blindness and decreased peripheral vision (also called “tunnel vision”). People with Usher syndrome develop RP at different ages depending upon the type (I, II, or III) diagnosed. Although most people with Usher syndrome have fairly good vision before they reach their 30s, it worsens slowly over time and approximately 75% of people in their 70s are blind.

Usher syndrome type I

People with Usher syndrome type I are born with profound SNHL that occurs in both ears. As a result, they do not learn to speak and typically learn to use sign language to communicate with others. Hearing aids usually are not very helpful, due to the amount of hearing loss present. However, some individuals benefit from a procedure called cochlear implantation, in which a small electronic device is surgically placed underneath the skin behind the ear and is attached to a wire that stimulates the inner ear, allowing people to hear useful sounds.

Usher syndrome type I also causes vestibular areflexia; this means affected individuals have balance problems because they cannot sense changes in direction or speed when they are moving. This causes children to more slowly develop certain skills that are required for movement and thus be clumsier and have a hard time with activities that require good balance, such as riding a bicycle. As affected people age, they tend to have an ataxic gait, which means they tend to stumble and shuffle their feet when walking.

The visual problems caused by RP usually develop during childhood among people with this type of Usher syndrome, and they gradually worsen over time. Usually the rod cells in the peripheral retina are affected first, causing night blindness and tunnel vision during childhood. Cone cells may eventually be affected causing blind spots to develop. Eventually, vision loss worsens and affected people can have vision problems during the day. Cataracts (cloudiness in the lens of the eye) may also develop and cause decreased central vision. Although most people with this type of Usher syndrome do not become completely blind, worsening vision may make communication via sign language and lip reading difficult.

Intellectual disability and psychiatric problems (such as depression, bipolar disorder, and psychosis) have been diagnosed in a number of people with Usher syndrome type I as well. Although some specialists believe that the stress of losing both hearing and vision may lead to psychological problems, at least one study has suggested that these problems may be due to an overall smaller brain size that has been measured in some affected individuals.

Hearing aids are medical devices that amplify sound for individuals experiencing hearing loss. (Paul Matthew Photography/Shutterstock)

Usher syndrome type II

People with Usher syndrome type II are born with mild to severe SNHL for low frequency sound that occurs in both ears. The SNHL is profound for higher frequency sounds. The amount of hearing loss is different between affected individuals, even those within the same family, although the ability to hear low frequency sound is often maintained. While hearing problems may worsen very slowly over time, speech therapy and the use of hearing aids are often helpful. Unlike people with type I, the vestibular system is not affected in people with Usher syndrome type II. Thus, they learn to walk in their first year as children and do not have problems with clumsiness. Although the symptoms of RP do occur among individuals with type II, they generally occur later in life during adolescence and adulthood. Symptoms also include night blindness, tunnel vision, blind spots, cataracts, and generally decreased vision. In addition, intellectual disability, psychiatric problems, and decreased brain size have been seen in some people with Usher syndrome type II.

Usher syndrome type III

People with Usher syndrome type III may be born with normal hearing or mild hearing loss, but their hearing loss is progressive, which means that it tends to worsen over time. The vestibular system causes mild balance problems that worsen over time. Older affected people may have balance problems similar to those seen in type I. There is a broad age range when the symptoms of RP occur among people with type III, although usually they happen later in life during the late teens to early adult years. Vision problems also worsen over time. In addition, intellectual disability and psychiatric problems also have been seen in some people with Usher syndrome type III.

People with Usher syndrome and their families often experience emotional and psychological distress.

Depression, anger, and grief are common among affected teenagers and adults. The vision and hearing problems create ongoing challenges for people in terms of their ability to receive information from the world and to effectively communicate with others. Affected people have to continually learn new skills, such as Braille or tactile sign language (i.e. using their hands to physically feel the signs), to adapt to their gradually worsening vision.

Genetic profile

Usher syndrome is inherited in an autosomal recessive manner. “Autosomal” means that males and females are equally likely to be affected. “Recessive” refers to a specific type of inheritance in which both copies of a person’s gene pair (i.e. both alleles) need to have a change or “mutation” in order for the disease to develop. In this situation, an affected individual receives a mutated copy of the same gene from each parent. If the parents are not affected, they each have one working copy of the gene and one nonworking (mutated) copy, and are only “carriers” for Usher syndrome. The chance that two carrier parents will have a child affected with Usher syndrome is 25% for each pregnancy. They also have a 50% chance to have an unaffected child who is simply a carrier, and a 25% chance to have an unaffected child who is not a carrier, with each pregnancy. In the United States, as many as 1 in every 70 people may be a carrier of a mutation that can lead to Usher syndrome.

Although there are three recognizable types of Usher syndrome, genetic research has shown that there are numerous genes located on different chromosomes that can all lead to Usher syndrome. This indicates that there is genetic heterogeneity among different families with Usher syndrome, meaning that different genes can lead to the same or similar disease among different families. As of 2006, researchers had identified six different subtypes of Usher syndrome type I (*USH1B*, *USH1C*, *USH1D*, *USH1E*, *USH1F*, and *USH1G*), four subtypes of Usher syndrome type II (*USH2A*, *USH2B*, *USH2C*, and *USH2D*), and one type of Usher syndrome type III (*USH3*). Although specific genes have been identified for only four of the eleven subtypes, the other seven have been linked to specific chromosomal regions. Two genes initially associated with the syndrome, *USH1A* and *USH2B*, have been removed from the list; *USH1A* was found to be incorrectly determined, and *USH1B* has yet to be verified as an Usher syndrome gene.

Genetic classification of Usher syndrome:

- *USH1B*—Located on chromosome 11q13.5. Specific gene called *myosin VIIA*.
- *USH1C*—Located on chromosome 11p15.1. Specific gene called *harmonin*.
- *USH1D*—Located on chromosome 10q21-22. Specific gene called *CDH23*.

- *USH1E*—Located on chromosome 21q21. Specific gene unknown.
- *USH1F*—Located on chromosome 10q11.2-q21. Specific gene called *protocadherin 15*.
- *USH1G*—Located on chromosome 17q24-q25. Specific gene called *SANS*.
- *USH2A*—Located on chromosome 1q41. Specific gene called *usherin*.
- *USH2C*—Located on chromosome 5q14.3-21.3. Specific gene called *VLGR1b*.
- *USH2D*—Chromosome location unknown. Specific gene called *whirlin*.
- *USH3*—Located on chromosome 3q21-25. Specific gene called *clarin-1*.

Although specific genes have been identified for some of the Usher syndrome subtypes, not all mutations in these genes lead specifically to Usher syndrome. For example, although mutations in *CDH23* can lead to Usher syndrome type 1D, some people who have certain types of mutations in both of their *CDH23* gene copies have a form of autosomal recessive deafness called DFNB12, in which affected individuals have profound SNHL at birth but do not have balance or vision changes that are typically seen in Usher syndrome.

Demographics

It is estimated that 2.5–4.5 per 100,000 people are affected with Usher syndrome in various countries including the United States, Denmark, Sweden, Norway, Finland, and Colombia, although it has been diagnosed in other parts of the world as well. There are some areas where Usher syndrome seems to be more common, including communities in northern Sweden and among the French Acadians in Louisiana. Certain types of Usher syndrome are more common in particular areas of the world as well. For example, among affected people in Finland, approximately 40% have type III. However, in the United States, types I and II are most common and occur with nearly equal frequency, while type III is very rare.

Signs and symptoms

Symptoms of Usher syndrome type I:

- Profound hearing loss at birth, causing lack of speech
- Lack of vestibular function at birth, leading to delayed ability to walk and increased clumsiness
- Retinitis pigmentosa in childhood, causing night blindness, tunnel vision, and decreased vision over time
- Intellectual disability or psychiatric problems in some people

Symptoms of Usher syndrome type II:

- Mild to severe hearing loss for low-frequency sound and profound hearing loss for high-frequency sound at birth
- Normal vestibular function, resulting in normal ability to maintain balance
- Retinitis pigmentosa in teens or early adult years, causing night blindness, tunnel vision, and decreased vision over time
- Intellectual disability or psychiatric problems in some people

Symptoms of Usher syndrome type III:

- Normal hearing or mild hearing loss at birth that worsens over time
- Abnormal vestibular function, causing mild balance problems that worsen over time
- Retinitis pigmentosa by teenage or early adult years, causing night blindness, tunnel vision, and decreased vision over time
- Intellectual disability or psychiatric problems in some people

Diagnosis

Although nine genes that cause Usher syndrome have been identified, genetic testing is not widely used to confirm a diagnosis. Some families do participate in genetic research studies by providing blood samples with the hope that useful information may be learned about their genetic mutations, as well as Usher syndrome in general.

The diagnosis of Usher syndrome is based on the results from a variety of tests that measure hearing, vision, and balance. Sometimes the diagnosis is not made until a person with SNHL reaches adolescence and develops vision problems. A follow-up eye examination may allow an eye care specialist to detect changes seen in RP, thus confirming the diagnosis of Usher syndrome. Specialized testing of an affected person's vestibular system can be done to help determine the type of Usher syndrome as well.

Treatment and management

There is currently no cure for Usher syndrome. Treatment regimens are palliative, addressing symptoms of the syndrome to improve the quality of life for patients.

Treatment and management of SNHL

Regular hearing exams are important to check for changes in hearing ability, especially for people with type II or type III Usher syndrome. Among people with milder

KEY TERMS

Central vision—The ability to see objects located directly in front of the eye. Central vision is necessary for reading and other activities that require people to focus on objects directly in front of them.

Cochlea—A bony structure shaped like a snail shell located in the inner ear. It is responsible for changing sound waves from the environment into electrical messages that the brain can understand, so people can hear.

Genetic heterogeneity—The occurrence of the same or similar disease, caused by different genes among different families.

Peripheral vision—The ability to see objects that are not located directly in front of the eye. Peripheral vision allows people to see objects located on the side or edge of their field of vision.

Photoreceptors—Specialized cells lining the innermost layer of the eye that convert light into electrical messages so that the brain can perceive the environment. There are two types of photoreceptor cells: rod cells and cone cells. The rod cells allow for peripheral and night vision. Cone cells are responsible for perceiving color and for central vision.

Retina—The light-sensitive layer of tissue in the back of the eye that receives and transmits visual signals to the brain through the optic nerve.

Retinitis pigmentosa—Progressive deterioration of the retina, often leading to vision loss and blindness.

Sensorineural hearing loss (SNHL)—Hearing loss that occurs when parts of the inner ear, such as the cochlea and/or auditory nerve, do not work correctly. It is often defined as mild, moderate, severe, or profound, depending upon how much sound can be heard by the affected individual.

Vestibular system—A complex organ located inside the inner ear that sends messages to the brain about movement and body position. It allows people to maintain their balance when moving by sensing changes in their direction and speed.

forms of hearing loss, hearing aids and speech therapy are often useful. Sign language training for people with profound SNHL and their families provides a method of communication, although these skills need to be modified into tactile sign language as vision decreases. Some people with severe to profound forms of hearing loss may have cochlear implants placed in an effort to improve their perception of sound.

QUESTIONS TO ASK YOUR DOCTOR

- When should hearing evaluations begin, and how often should they be repeated?
- Do you recommend vitamin A?
- What are the signs of vitamin A toxicity?
- What measures or resources do you recommend to improve quality of life?
- How likely is it that my children will be affected by my diagnosis?

Treatment and management of RP

People with night blindness, tunnel vision, and decreasing vision may benefit from a variety of techniques that help them cope with their ever-changing vision. The use of walking canes, guide dogs, magnifying lenses, flashlights, and Braille may be helpful. Specialized filtering lenses may decrease glare and make the eye more comfortable. Some people also find it useful to meet with low-vision specialists who can help them adapt to new lifestyle changes that help with daily living. Regular eye exams are important and allow early detection of cataracts, which may be treated with surgery.

Although there is no way to completely halt the symptoms of RP, studies published in the 1990s found that 15,000 IU of vitamin A palmitate can slow the course of the retinal changes among people with Usher syndrome type II. This therapy has not been recommended for people under 18 years of age; women who may become pregnant need to discuss with their doctor the potential harms that vitamin A can cause for a developing baby. People who want to take the vitamin should speak with their doctor first and have regular blood tests to check vitamin levels as well as to rule out liver problems caused by the supplement.

There are a number of support groups available that provide education, support, and helpful advice to help people cope with the symptoms of Usher syndrome.

Prognosis

Usher syndrome generally does not cause a shortened lifespan for affected individuals. Although people live for many years with Usher syndrome, the physical symptoms and emotional side effects change over time. The vision problems usually worsen slowly over the years, forcing people to adapt their lifestyles, modify their habits, and sometimes change professions. Regular eye exams can help diagnose cataracts that may be removed in an effort to maintain the

best vision possible. Regular monitoring of hearing may be helpful for people with mild, moderate, and/or severe hearing loss so that they can receive appropriate hearing aids. As vision problems (and sometimes hearing and/or balance problems) worsen, people are more likely to suffer emotionally due to decreasing quality of life and loss of independence. Many low-vision devices, lifestyle modifications, and various support groups often provide much-needed assistance to help maintain and/or improve quality of life for affected individuals.

Van der Woude syndrome

Definition

Van der Woude syndrome (VWS) is a condition affecting the lips, palate, and teeth. Depressions or pits typically are present on the lower lip at birth and cleft lip and/or cleft palate may also be present. Less commonly, certain teeth may not develop. VWS has previously been known as the lip pit syndrome.

Description

Van der Woude syndrome primarily involves pits developing on the lower lip, clefting of the lip and/or palate, and the absence of certain teeth. More than 80% (more than eight out of ten) individuals with VWS will develop pits near the center of the lower lip and about 60%–70% (six to seven people out of ten) will have a cleft lip and/or palate at birth. About one-half to two-thirds of the individuals will have both lower lip pits and a cleft of the lip and/or palate. In some cases, a cleft palate is present but is not immediately noticeable; this is called a submucosal cleft palate. The least common feature in VWS, missing teeth, is seen in about 10%–20% (one to two people out of ten) of individuals with VWS. The teeth most commonly affected are the second incisors and the second molars.

Van der Woude syndrome is related to another condition called popliteal pterygium syndrome (PPS). PPS is similar to VWS in that both conditions cause lip pits and cleft lip and/or palate to develop. PPS differs from VWS in that popliteal pterygium webs are present at birth. Pterygium means webbed skin. Popliteal refers to the back of the legs. Popliteal pterygium means that there is webbed skin on the back of the legs,

usually on the back of the knees. Individuals with PPS may also have underdevelopment of the genitals, webbing between the fingers, adhesion of the lower and upper eyelids, and fibrous bands attaching the lower and upper jaws.

Some families have features consistent with both VWS and PPS. In other words, within a family, some family members have features that are entirely consistent with VWS and other family members have features consistent with PPS.

Genetic profile

Mutations in the interferon regulatory factor 6 (*IRF6*) gene cause van der Woude syndrome. This gene, located on chromosome 1 at position 1q32.3–q41, provides instructions for making a protein that plays an important role in early development, particularly in cells associated with the growth of tissues in the head and face. A shortage of the IRF6 protein impairs the maturation of these tissues, resulting in the symptoms of van der Woude syndrome. The syndrome follows autosomal dominant inheritance, indicating that every individual affected by VWS has a 50% (1 in 2) chance of passing on the condition to each of his/her children. Every individual inheriting the VWS gene will develop at least one feature of VWS. However, family members may develop different features, and some may develop very minor features whereas another family member may have more severe problems. In some cases, a family member's features may be so mild that he or she is initially thought to be unaffected. Apparently unaffected parents of a newborn with VWS should undergo a thorough examination since it is possible that one of the parents is very mildly affected. If such a parent is determined to be affected, all of his or her children will have a 50% chance of inheriting VWS.

Mutations in the *IRF6* gene are also responsible for PPS, a congenital disorder that affects the face, skin, and genitals. Individuals with abnormalities of the *IRF6* gene

KEY TERMS

Autosomal dominant—A pattern of genetic inheritance where only one abnormal gene is needed to display the trait or disease.

Cleft—An elongated opening or slit in an organ.

Genetic test—Testing of chromosomes and genes from an individual or unborn baby for a genetic condition. Genetic testing can only be done if the gene is known.

Palate—The roof of the mouth.

Transcription factor—Proteins that activate or deactivate individual genes within the genome.

Ultrasound examination—Visualizing the unborn baby while it is still inside the uterus.

are also at a greater risk of being born with the isolated cleft lip, cleft palate, or both. These malformations are caused because of a deficiency of one of several proteins that are transcription factors, meaning that they help turn genes off and on during development. When these genes are not activated or when the wrong genes are activated, the facial features and other symptoms of VWS are created.

Demographics

According to the Office of Rare Diseases (ORD), van der Woude syndrome is a rare condition, meaning that it affects fewer than 200,000 people in the United States. Prevalence in the general European population is estimated at around 1 in 60,000.

Signs and symptoms

The primary symptom associated with VWS is the development of pits near the center of the lower lip (present in more than 80% of cases). In addition, 60%–70% of individuals with VWS also have cleft lip and/or cleft palate. A few individuals (about 10%–20%) with VWS are missing teeth; most commonly the second incisors and the second molars.

Diagnosis

As of 2009, diagnosis of VWS relied solely upon physical examination and whether or not the characteristic features of VWS are present or absent. The family history may also have an important role in determining the diagnosis. For example, if lower lip pits and a cleft palate are present in a newborn and no popliteal webs or other

feature of PPS is present, then the child has VWS. If a newborn is born with a cleft palate only but has a family history of VWS, then the child most likely has inherited VWS.

As cleft lip and/or palate occurs in other genetic conditions as well as by itself, a newborn with this birth defect needs to be fully evaluated to ensure that the reason for the cleft is correctly determined. Likewise, lower lip pits may be seen in VWS, in PPS, and rarely, in a third genetic condition called orofaciogigital syndrome, type 1; consequently, a baby born with lower lip pits needs to be fully evaluated.

Prenatal diagnosis for VWS can be attempted through ultrasound examination of unborn babies at risk for the condition. Cleft lip and very rarely cleft palate can be identified on ultrasound examination. However, as some clefts are small and some individuals with VWS do not have clefts at all, a normal ultrasound examination cannot completely rule out the chance the baby has inherited VWS. An ultrasound examination with high resolution, or a level 2 ultrasound, and an experienced technician may increase the chance of seeing cleft lips or palate. Lip pits cannot be seen on ultrasound examination, even with a higher resolution ultrasound.

Treatment and management

An individual with VWS will be treated and followed according to the features he or she has developed. The lip pits seen in VWS rarely cause problems. Occasionally, saliva may ooze from the pits and if so, a fistula may have developed. A fistula is an abnormal passage-way or opening, and in VWS, a fistula may develop between a salivary gland located under the lip and the lip surface. The pits and fistulas may be surgically removed.

If a cleft lip and/or palate is present, surgery will be necessary to correct this problem. The treatment and management of cleft lips and palates in individuals with VWS is no different from cleft lips and palates occurring in other genetic conditions or by themselves. The child will need to be followed closely for ear and sinus infections and hearing problems. The child may need speech therapy and should be followed by a dentist and orthodontist. Counseling may be needed as the child grows up to address any concerns about speech and/or appearance.

Prognosis

Overall, individuals with VWS do well. If a cleft lip and/or palate is present at birth, there may be some feeding difficulties in the newborn period and in the following

QUESTIONS TO ASK YOUR DOCTOR

- How is van der Woude syndrome diagnosed in a newborn child?
- What procedures are typically used for the treatment of this disorder?
- Does van der Woude syndrome result in serious mental or physical abnormalities later in life?
- How common is van der Woude syndrome in the United States?

three to six months, until the cleft is corrected. However, once surgery repairing the cleft is completed, the child typically does well. Van der Woude syndrome is not associated with a shorter lifespan.

VATER association

Definition

VATER association describes a pattern of related birth defects in the same infant involving three or more of the following: vertebrae (spine), anus and rectum, heart, trachea (windpipe), esophagus, radius (bone of the arm), and kidneys. Infants can have any combination of features, and there is a wide range of severity. Survival and medical complications depend on the extent and severity of features in each case.

Description

Doctors Linda Quan and David Smith first developed the term "VATER association" in 1973 to describe a similar pattern of birth defects in more than one infant. The problems at birth did not represent a certain syndrome but appeared to be associated since they were present in several babies. VATER is an acronym or abbreviation representing the first letter of each feature in the association: Vertebral (spine) abnormalities, Anal atresia (partial absence of the anus or unusual connection between anus and rectum), Tracheo-Esophageal fistula (connection between the windpipe and the tube carrying food from mouth to stomach), and Radial (bone of the forearm) or Renal (kidney) differences.

In the 1970s, some researchers expanded the VATER abbreviation to VACTERL. It was expanded to include cardiac (heart) abnormalities, and limb differences in general (differences in the arms and hands). In the expanded VACTERL, "L" includes radial differences and "R" represents kidney differences only. Both VATER and VACTERL are used to describe the same association of birth defects.

The exact cause of VATER is unknown. This is because VATER is rare and because the features vary from patient to patient. Many researchers agree that the cause of VATER occurs very early in the development of the embryo in order to affect so many organ systems. It is unknown whether VATER has a single cause or multiple causes during this early development process.

In the first couple of weeks after conception, a human embryo is a clump of cells that are unspecialized and full of potential. In the third week of pregnancy the embryo undergoes a process called gastrulation. This is when the cells of the embryo begin to group together in different areas. The different cell groups begin to specialize and prepare to form different organs and body parts. The mesoderm is the group of cells that organizes and eventually forms the baby's bones, muscles, heart, blood, kidneys, and reproductive organs. In the third week of

pregnancy, the notochord also develops. The notochord is the future spinal cord and gives the early embryo a center and stability. It may also have a role in organizing other cell groups. The primitive gut also organizes in the fourth week. The primitive gut undergoes more specialization and division into zones called the foregut, midgut, and hindgut. The esophagus (tube from mouth to stomach) and trachea (windpipe) develop from the foregut. The anus and rectum develop from the hindgut. The constant cell movement, grouping, and specialization is a precise process. Any interruption or damage in this early stage can affect multiple organs and body structures.

Some researchers believe the cause of VATER is a problem with gastrulation. Other researchers believe the error occurs when mesoderm cells begin to move to areas to begin specialization. Another theory is that the mesoderm receives abnormal signals and becomes disorganized. Other researchers believe more than one error occurs in more than one area of the early embryo to produce VATER. Some also believe an abnormality of the notochord is involved in the development of VATER.

One group of researchers has discovered that pregnant rats that are given a toxic drug called Adriamycin have offspring with birth defects very similar to those seen in humans with VATER. This has allowed the researchers to study normal and abnormal development of the early embryo. The study of rats showed abnormal notochord development in offspring with connections of the trachea and esophagus. In those offspring, the notochord was thickened and connected unusually to the foregut. More research of this animal model will answer many questions about the development and cause of the features of VATER.

Genetic profile

The exact genetic cause of VATER association is unknown. Most cases are sporadic and do not occur more than once in the same family. This was determined by studies of families with an affected individual. Since cases are rare and most are isolated in a family, studies to find a genetic cause have been unsuccessful. Parents of a child with VATER association have a 1% or less chance of having another baby with the same condition. There have been a few reports of affected individuals with a parent or sibling showing a single feature of the VATER spectrum. There has only been one reported case of a parent and child both affected with multiple VATER features.

Most individuals with VATER association have a normal chromosome pattern. However, a few cases of chromosome differences have been reported in individuals with VATER. One child with VATER had a deletion (missing piece) on the long arm of chromosome 6.

Another male infant had a deletion on the long arm of chromosome 13. There have been other children reported with a chromosome 13 deletion and VATER-like features. This infant was the first reported with the deletion to have all of the VACTERL main features. He was also the first with this chromosome deletion to have a connection between his trachea and esophagus. Another child with VATER association had an extra marker chromosome. This is a fragment of chromosomal material present in the cell in addition to the usual 46 chromosomes. This child's marker was found to contain material from chromosome 12. These cases have not led to the discovery of a gene involved in VATER.

There has only been one VATER case reported in which a genetic change was identified. That female infant died one month after birth because of kidney failure. Her mother and sister later were diagnosed with a mitochondrial disease. Mitochondria are the structures in the cell that create energy by chemical reactions. The mitochondria have their own set of DNA, and a person inherits mitochondrial DNA from the mother only. Stored kidney tissue from the deceased infant was analyzed and she was found to have the same genetic change in her mitochondrial DNA, as her mother and sister. The researchers could not prove that the gene change caused the infant's features of VATER.

There are two subtypes of VACTERL that seem to be inherited. Both types have the typical VACTERL features in addition to hydrocephaly (excess water in the brain). They are abbreviated VACTERL-H. The first subtype was described in 1975 by David and O'Callaghan and is called the David-O'Callaghan subtype. It appears to be an autosomal recessive condition. Parents of an affected child are carriers of a normal gene and a gene that causes VACTERL-H. When both parents are carriers, there is a 25% chance for an affected child with each pregnancy. The second subtype is called Hunter-MacMurray and appears to be an X-linked recessive condition. In X-linked conditions, the disease-causing gene is located on the X chromosome, one of the sex-determining chromosomes. Females have two X chromosomes and males have an X chromosome and a Y chromosome. A female who carries a disease-causing gene on one of her X chromosomes shows no symptoms. If a male inherits the gene he will show symptoms of the condition. A woman who carries the VACTERL-H X-linked gene has a 25% chance of having an affected son with each pregnancy. Both of these subtypes are rare and account for a small number of VACTERL cases.

Demographics

VATER is rare, but has been reported worldwide. Exact incidence can be difficult to determine because of

different criteria for diagnosis. Some studies consider two or more VATER features enough to make the diagnosis. Other studies require at least three features to diagnose VATER. Also, infants with features of VATER may have other genetic syndromes such as trisomy 13, trisomy 18, Holt-Oram syndrome, TAR syndrome, and Fanconi anemia. VATER does appear to be more frequent in babies of diabetic mothers. It is also more frequent in babies of mothers taking certain medications during pregnancy, including estroprogestins, methimazole, and doxorubicin.

Signs and symptoms

VATER has six defining symptoms. “V” represents vertebral abnormalities. Approximately 70% of individuals with VATER have some type of spine difference such as scoliosis (curvature of the spine), hemivertebrae (unusually aligned, extra, or crowded spinal bones), and sacral absence (absence of spinal bones in the pelvic area). Vertebral differences are usually in the lumbosacral area (the part of the spine in the small of the back and pelvis). “A” represents anal atresia which is present in about 80% of individuals with VATER. This is an unusual arrangement or connection of the anus and rectum. Imperforate anus is also common, in which the anal opening does not form or is covered. Babies with this problem cannot pass bowel movements out of the body. “TE” stands for tracheo-esophageal fistula. About 70% of babies with VATER have this problem. This is a connection between the two tubes of the throat: the esophagus (carries food from mouth to stomach) and the trachea (windpipe). This connection is dangerous because it causes breathing problems. These babies can also get food into their windpipe and choke. Lung infections are also common with this connection. Some infants may be missing part of their esophagus, causing problems with choking and feeding. These babies spit up their food because the food cannot get to the stomach.

In the original VATER association, “R” stood for radial differences and renal (kidney) problems. The radius is the forearm bone that connects to the hand on the side of the thumb. Radial differences can include an absent or underdeveloped radius. This often results in a twisted, unusual position of the arm and hand. The thumb can also be small, misplaced, or absent. Kidney problems are present in about half of individuals with VATER. These can include missing kidneys, kidney cysts, or fluid buildup in the kidneys. Some individuals also have an abnormal position of the urethra (the tube that carries urine out of the body).

The expanded VACTERL includes “C” for cardiac (heart) problems and “L” for limb differences. The heart problems are usually holes or other structural abnormalities. Limb differences usually involve the arms rather

KEY TERMS

Anus—The opening at the end of the intestine that carries waste out of the body.

Fistula—An abnormal passage or communication between two different organs or surfaces.

than the legs. The term includes more general differences such as extra fingers, shortened or missing fingers, and underdeveloped humerus (the bone of the upper arm). These differences often cause unusual arm or hand positions (bent or twisted) and fingers that are short, absent, or misplaced.

Many people have proposed an expanded VACTERL pattern to include differences of the reproductive system and absent sacrum. Small or ambiguous (not clearly male or female) genitalia, or misplaced reproductive parts are common in VACTERL. They tend to occur more frequently in infants with anal and kidney abnormalities. They are seen less often with esophagus and arm features. Absence of the bones of the sacrum (spine in the pelvis area) is also commonly seen in VACTERL.

Individuals with VATER have an average of seven to eight features or differences at birth. About two-thirds of features involve the lower body (intestines, genitals, urinary system, pelvis, and lower spine). One-third of features involve the upper body (arms, hands, heart, esophagus, and trachea). In addition to the typical VATER features, infants may have problems with the intestines or excess water in the brain. Intestinal problems (such as missing sections of intestine) are more common in individuals with anal or esophagus features.

Shortly after birth, infants with VATER often have failure to thrive. This involves feeding problems and difficulty gaining weight. Their development is often slow. Infants with visible signs of VATER should immediately be checked for internal signs. Quick detection of problems with the trachea, esophagus, heart, and kidneys can lead to earlier treatment and prevention of major illness. Most individuals with VATER have normal mental development and mental retardation is rare.

Diagnosis

Some features of VATER can be seen on prenatal ultrasound so that the diagnosis may be suspected at birth. Ultrasound can see differences of the vertebrae, heart, limbs, limb positions, kidneys, and some reproductive parts. Other problems that are associated with VATER on ultrasound are poor fetal growth, excessive

QUESTIONS TO ASK YOUR DOCTOR

- What are the risks and benefits for the surgical procedures?
- When should my baby be tested to see whether internal disorders are present?
- Do you recommend orthopedic devices?
- Which family members should undergo genetic testing?

fluid in the womb, absent or collapsed stomach, and one artery in the umbilical cord instead of the usual two. VATER features that cannot be seen on ultrasound are differences of the anus, esophagus, and trachea.

Even if VATER is suspected before birth, an infant must be examined after birth to determine the extent of features. The entire pattern of internal and external differences will determine if the infant has VATER association, another multiple birth defect syndrome, or a genetic syndrome (such as Holt-Oram syndrome, TAR syndrome, or Fanconi anemia). Since VATER overlaps with some genetic syndromes, some infants may fit the VATER pattern and still have another diagnosis. VATER only describes the pattern of related birth defects. Since the genetic causes of VATER are unknown, genetic testing is not available. A family history focusing on VATER features can help to determine if an infant has a sporadic case or a rare inherited case.

Treatment and management

Treatment for VATER involves surgery for each separate feature. Holes in the heart can be closed by surgery. Structural problems of the heart can also often be repaired. Prognosis is best for infants with small or simple heart problems. Some vertebral problems may also need surgery. If the vertebral differences cause a problem for the individual's posture, braces or other support devices may be needed.

Problems with the trachea and esophagus can also be repaired with surgery. Before surgery the infant usually needs a feeding tube for eating. This will stop the choking and spitting up. The infant may also need oxygen to help with breathing. If the trachea and esophagus are connected, the connection is separated first. Once separated, the two trachea ends and esophagus ends can be sealed together. When part of the esophagus is missing, the two loose ends are connected. If the gap between the loose ends is too big, surgery may be delayed until the

esophagus grows. Some infants still have problems after surgery. They may have a difficult time swallowing or food may get stuck in their throat. They may also have asthma and frequent respiratory infections.

Surgery can also repair problems of the anus and rectum. Before surgery, a temporary opening is made from the small intestine to the abdomen. This allows the infant to have bowel movements and pass stool material. An anal opening is created with surgery. The intestines and rectum are adjusted to fit with the new anal opening. The temporary opening on the abdomen may be closed immediately after surgery or it may be closed weeks or months later. Surgeons must be very careful not to damage the nerves and muscles around the anus. If they are damaged, the individual may lose control of their bowel movements.

Differences of the hands and arms can also be improved with surgery. Infants with underdeveloped or absent radius may have a stiff elbow, stiff wrist, or twisted arm. Surgery can loosen the elbow and wrist to allow for movement. The arm can also be straightened. If needed, muscles from other parts of the body can be put into the arm. This may also improve movement. Even after surgery, individuals may not have completely normal function of the muscles and tendons of the arms and hands.

Prognosis

Prognosis for individuals with VATER association depends on the severity of features. Infants with complex heart problems or severe abnormalities of the anus, trachea, or esophagus have a poorer prognosis. Infants with several features that require surgery have a higher death rate than infants that need minor surgery or no surgery. Survival also depends on how quickly internal problems are discovered. The sooner problems with the heart, anus, trachea, and esophagus are found and repaired, the better the outlook for the infant. One study estimated that infants with VATER have a death rate 25 times higher than healthy infants. Another study estimated that up to 30% of individuals with VATER die in the newborn period.

Viral variant

Definition

A viral variant contains a specific variation (mutation) in its genetic material that makes it different from the virus it originated from. Variants result from errors when the virus replicates, or makes copies of itself. Recombination is another important element in viral variation. Recombination involves mutations occurring in multiple variants that combine during replication to create a newer and sometimes more durable variant or strain of the virus.

Description

In order to replicate, a virus must duplicate its genetic material. The genetic material of SARS-CoV-2, the virus that causes COVID-19 is ribonucleic acid (RNA). It is called an RNA virus. Some viruses, called DNA viruses, have deoxyribonucleic acid (DNA) as their genetic material. Humans have both RNA and DNA.

Viral RNA and DNA contain genes that are the instructions for the creation of proteins. Proteins guide the development and functioning of a virus. The simplest viruses have only enough DNA or RNA to create four

KEY TERMS

DNA—The genetic material that contains the instructions for creating proteins.

DNA virus—A virus whose genetic material is deoxyribonucleic acid (DNA). The instructions from DNA are transcribed into RNA.

Gene—A gene is the unit of information on DNA that contains the instructions for making one protein.

Host—The body that A virus has infected.

Mutation rate.—How often a virus makes errors when copying itself.

Protein—Proteins are the building blocks for life. They guide the development and functioning of a virus.

Replication—The process by which a virus makes copies of itself.

RNA—The genetic material that is involved in creating proteins.

RNA virus—A virus whose genetic material is ribonucleic acid (RNA).

proteins, while more complex viruses have instructions for hundreds of proteins. The DNA holds the instructions for developing proteins but does not create the proteins. In DNA viruses, some of the information from the DNA is transcribed into a molecule called RNA. The pieces of DNA that are transcribed into RNA are called genes. For RNA viruses, the genes are already present in the RNA. In either case, the RNA instructions are converted into proteins.

Because viruses are not much more than genetic material wrapped in a protein shell and sometimes an envelope, they possess genes that allow them to hijack the host's cellular machinery. Viruses use this machinery to help with replication.

Errors can sometimes happen during replication, resulting in a change in the genetic material and a new variant. In some cases, the change is so minor that it doesn't change the virus significantly. If the change is significant and changes the way the virus acts, then it is sometimes called a variant of concern or significance. For example, a variant of concern can be more infectious or more deadly than the original virus. Variants that are more infectious or are more resistant to vaccines often become dominant, since they can outcompete other variants. For example, during the COVID-19 pandemic,

QUESTIONS TO ASK YOUR DOCTOR

- Are there any new treatments for my viral infection?
- How often will I need to be vaccinated?
- What side effects should I watch out for with this vaccine?

variants like the Alpha variant (UK) and the Delta variant (India) spread more quickly than the original virus, since they were 50 to 60 percent better at moving from person to person (transmission). Scientists at the Los Alamos Laboratory in New Mexico documented at least one recombination event involving the SARS-CoV-2 virus in early 2021, a combination derived from the Alpha variant from the U.K. and the Beta variant from California. The resulting variant did not become dominant or circulate widely. Researchers have also presented evidence that the evolution of SARS-CoV-2 and spillover to humans could have been the result of recombination of coronaviruses hosted by pangolins and bats.

The more people who are infected with a virus, the more likely there will be new variants. This is because every time a virus replicates, there is a chance that a new variant will result. New variants may be more likely to occur in patients who are ill for a long period of time or who undergo treatment that forces the virus to mutate in an attempt to evade destruction.

A new strain of a virus is a variant that has very different characteristics. For example, the original SARS-CoV-2 virus is a new strain of the coronavirus. Most coronaviruses cause mild to moderate respiratory conditions like the cold. SARS-CoV-2, on the other hand, causes COVID-19, which is a more deadly infection that affects many different systems in the body.

Vaccines and variants

How easy it is to create a vaccine, and how often you need to be vaccinated depend, in part, on how quickly a virus makes variants. This is called the mutation rate. DNA viruses have lower mutation rates than RNA viruses, since they tend to create variants less often than RNA viruses do. DNA viruses, like smallpox, have a lower mutation rate, since they make a protein called polymerase, which fixes many of the errors that happen during replication. RNA viruses, on the other hand, tend to have higher mutation rates. The mutation rate of RNA

viruses can be a million times higher than the that of human DNA.

The higher the mutation rate, the more difficult it can be to create a lasting vaccine against a virus. Usually the vaccine also needs to be changed frequently to fight viruses that have high mutation rates. Influenza, an RNA virus, has a high mutation rate and requires yearly vaccinations. Vaccine manufacturers have to adjust their vaccine to fight the influenza variant(s) that they think will be dominant in a particular year. Smallpox only required one vaccination, on the other hand, because it has a low mutation rate. That is also one of the reasons why we were able to eradicate smallpox completely, and we no longer require vaccinations against this disease.

SARS-CoV-2 is a coronavirus. Coronaviruses have a slightly lower mutation rate than some other RNA viruses, because they are able to fix some of the errors that happen during replication. They appear to have a higher mutation rate than smallpox. The exact mutation rate of SARS-CoV-2 is unknown, and scientists are unsure of how often the COVID-19 vaccines will need to be modified and how often we will need booster shots.

Von Hippel-Lindau syndrome

Definition

Von Hippel-Lindau (VHL) syndrome is an inherited condition characterized by tumors that arise in multiple locations in the body. Some of these tumors cause cancer and some do not. Many of the tumors seen in VHL are

(Gale)

vascular, meaning that they have a rich supply of blood vessels.

Description

In the mid-1800s, ophthalmologists described vascular tumors in the retina, the light-sensitive layer that lines the interior of the eye. These tumors, called angiomas, were not cancerous but were associated with vision loss. In 1904, a German ophthalmologist named Eugen von Hippel noted that these retinal angiomas seemed to run in families. Twenty-three years later, Arvid Lindau, a Swedish pathologist, reported a connection between these retinal angiomas and similar tumors in the brain, called hemangioblastomas. Like angiomas, hemangioblastomas are vascular tumors. After Lindau noted this association, there were many more reports describing families in which there was an association of retinal angiomas and central nervous system (CNS) hemangioblastomas. Other findings were found to be common in these families as well. These findings included cysts and/or tumors in the kidney, pancreas, adrenal gland, and various other organs. In 1964, Melmon and Rosen wrote a review of the current knowledge of this condition and named the disorder von Hippel-Lindau disease. More recently, the tumors in the retina were determined to be identical to

those in the CNS. They are now referred to as hemangioblastomas, rather than angiomas.

There are four distinct types of VHL, based on the manifestations of the disorder. Type 1 is characterized by all VHL-related tumors except those in the adrenal gland. Type 2 includes tumors of the adrenal gland and is subdivided into type 2A (without kidney tumors or cysts in the pancreas), type 2B (with kidney tumors and cysts in the pancreas), and type 2C (adrenal gland tumors only).

Genetic profile

VHL is inherited in an autosomal dominant manner. This means that an affected person has a 50% chance of passing the disease on to each of his or her children. Nearly everyone who carries the mutation in the *VHL* gene will show signs of the disorder, the average of about 26 years of age and most by 65 years of age.

VHL is caused by a change or mutation in the *VHL* gene. This gene is located on chromosome 3 and produces the VHL protein. The VHL protein is a tumor suppressor, meaning that it controls cell growth. When the *VHL* gene is changed, the VHL protein does not function correctly and allows cells to grow out of control. This

KEY TERMS

Adrenal gland—A triangle-shaped endocrine gland, located above each kidney, that synthesizes aldosterone, cortisol, and testosterone from cholesterol. The adrenal glands are responsible for salt and water levels in the body, as well as for protein, fat, and carbohydrate metabolism.

Angioma—A benign tumor composed of blood vessels or lymph vessels.

Benign—A non-cancerous tumor that does not spread and is not life-threatening.

Bilateral—Relating to or affecting both sides of the body or both of a pair of organs.

Broad ligament—The ligament connecting the ovaries to the uterus.

Computed tomography (CT) scan—An imaging procedure that produces a three-dimensional picture of organs or structures inside the body, such as the brain.

Cyst—An abnormal sac or closed cavity filled with liquid or semisolid matter.

Epididymis—Coiled tubules that are the site of sperm storage and maturation for motility and fertility. The epididymis connects the testis to the vas deferens.

Hemangioblastoma—A tumor of the brain or spinal cord arising in the blood vessels of the meninges or brain.

Hormone—A chemical messenger produced by the body that is involved in regulating specific bodily functions such as growth, development, and reproduction.

Magnetic resonance imaging (MRI)—A technique that employs magnetic fields and radio waves to create detailed images of internal body structures and organs, including the brain.

Mutation—A permanent change in the genetic material that may alter a trait or characteristic of an individual, or manifest as disease, and can be transmitted to offspring.

Pancreatic islet cell—Cells located in the pancreas that serve to make certain types of hormones.

Pheochromocytoma—A small vascular tumor of the inner region of the adrenal gland. The tumor causes uncontrolled and irregular secretion of certain hormones.

Renal cell carcinoma—A cancerous tumor made from kidney cells.

Retina—The light-sensitive layer of tissue in the back of the eye that receives and transmits visual signals to the brain through the optic nerve.

uncontrolled cell growth forms tumors, and these tumors may lead to cancer.

People without VHL have two working copies of the *VHL* gene, one on each chromosome 3. Each of these copies produces the VHL protein. People affected with VHL inherit one working copy and one non-working copy of the gene. Thus, one gene does not make the VHL protein but the corresponding gene on the other chromosome continues to make the functional protein. In this case, cell growth will still be controlled because the VHL protein is available. However, as this person lives, another mutation may occur in the working gene. If this happens, the VHL protein can no longer be made. Cell growth cannot be controlled and tumors develop. Mutations like this occur in various organs at various times, leading to multiple tumors forming in distinct parts of the body over a period of time.

The majority of patients with VHL syndrome inherited the mutation from one of their parents. In approximately 20% of cases, there is no family history of the disorder and VHL occurs because of a new mutation in

the affected individual, termed a *de novo* mutation. If a person appears to be an isolated case, it is important that the parents have genetic testing. It is possible that a parent could carry the mutation in the *VHL* gene but have tumors that do not cause any noticeable symptoms. If a parent is affected, each of his or her future children would have a 50% of being affected with VHL. If both parents test negative for the *VHL* gene mutation, each future child has a 5% risk of inheriting VHL. This small risk is to account for the rare possibility that one parent carries the mutation in his or her sex cells (egg or sperm) but does not express the disorder in any of the other cells of the body.

Demographics

VHL occurs in approximately 1 in 36,000 live births. It is seen in all ethnic groups and both sexes are affected equally.

Signs and symptoms

There are several characteristic features of VHL but no single, unique finding. Thus, it is necessary that many

different specialties be involved in the diagnosis and management of the disease. This approach will ensure proper, thorough care for these patients.

VHL is characterized by hemangioblastomas, tumors that arise in the blood vessel. These tumors are found in the central nervous system, or the brain and spinal cord. They most commonly present between the ages of 25 and 40 years and are the first symptom of VHL in 40% of cases. It is common to see multiple tumors. They may appear at the same time or at different times. These tumors generally grow slowly but, in some cases, may enlarge more rapidly. Hemangioblastomas seen in VHL are benign (non-cancerous) but may produce symptoms depending on their size, site, and number. Hemangioblastomas in the brain may lead to headache, vomiting, slurred speech, or unsteady and uncoordinated movements. These symptoms are usually due to the tumors disrupting brain function or causing increased pressure in the brain. Hemangioblastomas of the spine are usually accompanied by pain, and can lead to loss of sensation and motor skills. Some of these tumors may fail to cause any observable symptoms.

In patients with VHL, hemangioblastomas also appear in the retina, the light-sensitive layer that lines the interior of the eye. These tumors occur in approximately half the cases of VHL and may be the first sign that a person is affected. It is common to see numerous retinal hemangioblastomas develop throughout a person's lifetime. They often can be found in both eyes. These tumors have been detected as early as the age of four years but are more typically found between the ages of 21 and 28 years. They often occur without symptoms, but can be detected on a routine eye exam. If untreated or undetected, they may cause the retina to detach from the eye. This condition is accompanied by bleeding and leads to vision loss and possibly blindness.

Approximately 50%–70% of individuals with VHL also have numerous cysts on their kidneys. Cysts are sacs or closed cavities filled with liquid. In VHL, these cysts are vascular and frequently occur in both kidneys; however, they rarely result in noticeable symptoms. In some cases, these cysts may develop into renal cell carcinomas. These are cancerous tumors that are composed of kidney cells. Seventy percent of people affected with VHL will develop this type of kidney tumor during their lifetime. This type of cancer is generally diagnosed between the ages of 41 and 45 years. By the time this condition produces symptoms, it is likely that the cancer has already spread to other parts of the body. If this is the case, the tumors will respond poorly to chemotherapy and radiation, two common cancer treatments.

VHL can also cause multiple cysts in the pancreas. These occur at the average age of 41 years and are vascular in nature. Pancreatic cysts rarely cause problems and tend to grow fairly slowly. Pancreatic islet cell tumors can occur as well but are unrelated to the cysts. Islet cells in the pancreas produce hormones. Hormones are substances that are produced in one organ and then carried through the bloodstream to another organ where they perform a variety of functions. When tumors occur in the islet cells of the pancreas, these cells secrete too many hormones. This increase in hormones rarely leads to recognizable symptoms. Pancreatic islet cell tumors grow slowly and are non-cancerous.

Additionally, tumors in the adrenal gland, called pheochromocytomas, are common in VHL. The adrenal glands are located on top of each kidney. They secrete various hormones into the bloodstream. Pheochromocytomas are made of cells from the inner region of the adrenal gland. These tumors are benign, but can be numerous and are often located in both adrenal glands. They can be confined to the inside of the adrenal gland, or they can travel and appear outside of it. Some do not cause any observable symptoms. Others can lead to high blood pressure, sweating, and headaches.

In approximately 10% of cases, tumors can also be found in the inner ear. Most often, these tumors occur in both ears. They may lead to hearing loss of varying severity. This hearing loss may be one of the first signs that an individual is affected with VHL. Less commonly, a person may complain of dizziness or a ringing in the ear due to these inner ear tumors.

Men with VHL commonly have tumors in the epididymis. The epididymis is a structure that lies on top of the testis and serves as the site for sperm storage and maturation for motility and fertility. If these tumors occur bilaterally, they can lead to infertility. However, as a general rule, they do not result in any health problems. The equivalent tumor in females is one that occurs in the broad ligament. This ligament connects the ovaries to the uterus. These tumors, however, are much less common than those in the epididymis.

It is important to note that wide variation exists among all individuals affected with VHL in regard to the age of onset of the symptoms, the organ systems involved, and the severity of disease.

Diagnosis

VHL can be diagnosed clinically, with or without genetic testing. If a person has no family history of the disorder, a diagnosis of VHL can be made if one of the following criteria are met:

- the patient has two or more hemangioblastomas of the retina or CNS
- the patient has a single hemangioblastoma along with one of the other tumors or cysts that are commonly associated with the disorder.

A diagnosis of VHL can also be established in a person who has a positive family history of the disorder if they show one or more of the following before the age of 60:

- retinal hemangioblastoma
- CNS hemangioblastoma
- pheochromocytoma
- multiple pancreatic cysts
- tumor of the epididymis
- multiple renal cysts
- renal cell carcinoma
- endolymphatic sac tumors

Several tests are available that can assist in the diagnosis of VHL. They can also determine the extent of symptoms if the diagnosis has already been made. A computed tomography (CT) scan or magnetic resonance imaging (MRI) is often utilized for these purposes. These procedures serve to produce images of various soft tissues in the body, such as the brain and abdominal area. In someone with VHL, they are used to assess for the presence of CNS hemangioblastomas and other tumors associated with the disorder, such as pheochromocytomas and inner ear tumors. Pheochromocytomas may also cause abnormal substances to be released into the urine. A urinalysis can detect these substances and, therefore, suggest the existence of these tumors. Additionally, ultrasound examination can assist in evaluating the epididymis, broad ligament, and kidneys. Ultrasound examination involves the use of high frequency sound waves. These sound waves are directed into the body and the echoes of reflected sound are used to form an electronic image of various internal structures.

VHL can also be diagnosed via examination of the *VHL* gene on the molecular level. This type of testing detects approximately 90%–100% of people who are affected with the disorder and is indicated for confirmation of the diagnosis in cases of suspected or known VHL. Molecular genetic testing examines the *VHL* gene and detects any mutations, or changes in the gene. Most often, in this disorder, the gene change involves a deletion of a part of the gene or a change in one of the bases that makes up the genetic code.

Since molecular testing is so accurate, it is recommended even in cases where the clinical criteria for diagnosis are not met. It is possible that the tumors associated

QUESTIONS TO ASK YOUR DOCTOR

- How frequently should we evaluate for the presence of tumors?
- What tests do you recommend?
- When should gene testing be performed?
- When should renal testing be performed, and how often should it be repeated?

with VHL are present but are not causing any observable symptoms. Thus, even if a person does not meet the diagnostic criteria mentioned above, molecular testing can be used as a means of “ruling out” VHL with a high degree of certainty. For patients with numerous, bilateral pheochromocytomas, or for those who have a family history of these tumors, molecular testing is strongly suggested since these tumors may be the only signs of the disorder in those with VHL type 2C.

VHL can be diagnosed at various ages, ranging from infancy to the seventh decade of life or later. The age of diagnosis depends on the expression of the condition within the family, and whether or not asymptomatic lesions are detected.

Treatment and management

There is no treatment for VHL because the genetic defect cannot be fixed. Management focuses on routine surveillance of at-risk and affected individuals for early detection and treatment of tumors.

For at-risk relatives of individuals diagnosed with VHL, molecular genetic testing is recommended as part of the standard management. If a person tests negative for the mutation, costly screening procedures can be avoided. If an at-risk relative has not been tested for the mutation, surveillance is essential for the early detection of signs of VHL.

The following groups of people should be routinely monitored by a physician familiar with VHL:

- individuals diagnosed with VHL
- individuals who are asymptomatic but who have tested positive for a mutation in the *VHL* gene
- individuals who are at-risk due to a family history of the disorder but have not undergone molecular testing

For these groups of people, annual physical examinations are recommended, along with neurologic evaluation for signs of brain or spinal cord tumors. Additionally, blood pressure screening and an eye exam

should be completed annually, beginning around one year of age. These exams can detect retinal hemangioblastomas, which often produce no clinical symptoms until serious damage occurs. Beginning at the age of five, in addition to the screenings started at age one, urinary screening for fractionated metanephrines should be performed yearly, and auditory screening should be performed every two to three years, particularly in those with recurrent inner ear infections. When a person reaches the age of 16, an abdominal ultrasound should be completed annually as well. Any suspicious findings should be followed up with a CT scan or MRI. If pheochromocytomas are in the family history, blood pressure should be monitored annually. Although the majority of tumors associated with VHL are benign in nature, they all have a small possibility of becoming cancerous. For this reason, surveillance and early detection is very important to the health of those affected with VHL.

If any tumors are identified by the above surveillance, close monitoring is necessary and surgical intervention may be recommended. Hemangioblastomas of the brain or spine may be removed before they cause symptoms. They may also be followed with yearly imaging studies and removed only after they begin to cause problems. Most of these tumors require surgical removal at some point and results are generally good. Retinal hemangioblastomas can be treated with various techniques that serve to decrease the size and number of these tumors.

Early surgery is recommended for renal cell carcinoma (RCC). Extreme cases may require removal of one or both kidneys, followed by a transplant. Additionally, studies have proposed further trials should be done for the treatment of RCC in patients with VHL via oral drugs such as Sunitinib, which is a multitargeted receptor tyrosine kinase inhibitor with antiangiogenic and antitumor activity. This drug has shown success in patients with RCC and may be effective in patients with RCC due to VHL. Additionally, pheochromocytomas should be surgically removed if they are causing symptoms. Inner ear tumors, however, generally are slow-growing. The benefit of removing one of these tumors must be carefully compared to the risk of deafness, which may result from the surgery. Epididymal and broad ligament tumors generally do not require surgery.

Prognosis

The average life expectancy of an individual with VHL is 49 years. Renal cell carcinoma is the leading cause of death for affected individuals. If an affected person is diagnosed with renal cell carcinoma, their average life expectancy decreases to 44.5 years. CNS hemangioblastomas are responsible for a significant proportion of

deaths in affected individuals as well, due to the effects of the tumor on the brain.

von Willebrand disease

Definition

Von Willebrand disease is caused by a deficiency or an abnormality in a protein called von Willebrand factor (VWF) and is characterized by prolonged bleeding.

Description

The Finnish physician Erik von Willebrand was the first to describe von Willebrand disease (VWD). In 1926 Dr. von Willebrand noticed that many male and female members of a large family from the Åland Islands had increased bruising (bleeding into the skin) and prolonged episodes of bleeding. The severity of the bleeding varied between family members, ranged from mild to severe, and typically involved the mouth, nose, genital and urinary tracts, and occasionally the intestinal tract. Excessive bleeding during the menstrual period was also experienced by some of the women in this family. What

von Willebrand Disease: pedigree analysis chart (Gale)

differentiated this bleeding disorder from classical hemophilia was that it appeared not to be associated with muscle and joint bleeding and affected women and men rather than just men. Dr. von Willebrand named this disorder hereditary pseudohemophilia.

Pseudohemophilia, or von Willebrand disease (VWD) as it is now called, is caused when the body does not produce enough of a protein called von Willebrand factor (VWF) or produces abnormal VWF. VWF is involved in the process of blood clotting (coagulation). Blood clotting is necessary to heal an injury to a blood vessel. When a blood vessel is injured, VWF enables blood cells called platelets to bind to the injured area and form a temporary plug to seal the hole and stop the bleeding. VWF is secreted by platelets and by the cells that line the inner wall of the blood vessels (endothelial cells). The platelets release other chemicals, called factors, in response to a blood vessel injury, which are involved in forming a strong permanent clot. VWF binds to and stabilizes factor VIII, one of the factors involved in forming the permanent clot.

A deficiency or abnormality in VWF can interfere with the formation of the temporary platelet plug and also affect the normal survival of factor VIII, which can indirectly interfere with the production of the permanent clot. Individuals with VWD, therefore, have difficulty in

forming blood clots and, as a result, they may bleed for longer periods of time. In most cases the bleeding is due to an obvious injury, although it can sometimes occur spontaneously.

VWD is classified into three basic types: type 1, 2, and 3, based on the amount and type of VWF that is produced. Type 1 is the most common and mildest form, and results when the body produces slightly decreased amounts of typically normal VWF. Type 2 can be classified into four subtypes (A, B, M, N) and results when the body produces an abnormal type of VWF. Type 3 is the rarest and most severe form, and results when the body does not produce any detectable VWF.

Genetic profile

The genetics of VWD are complex and involve a gene that produces VWF and is found on chromosome 12. Since individuals inherit two of each type of chromosome, they inherit two *VWF* genes. There are different types of changes in the *VWF* gene that can affect its production. Some types of changes can cause the *VWF* gene to produce decreased amounts of normal VWF, while other changes can cause the gene to produce abnormal VWF. Most of the gene changes are significant enough that a change in only one *VWF* gene is sufficient to cause VWD. Some gene changes only cause VWD if both

KEY TERMS

Amniocentesis—A procedure performed at 16–18 weeks of pregnancy in which a needle is inserted through a woman's abdomen into her uterus to draw out a small sample of the amniotic fluid from around the baby. Either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Autosomal dominant—A pattern of genetic inheritance where only one abnormal gene is needed to display the trait or disease.

Autosomal recessive—A pattern of genetic inheritance where two abnormal genes are needed to display the trait or disease.

Biochemical testing—Measuring the amount or activity of a particular enzyme or protein in a sample of blood, urine, or other tissue from the body.

Carrier—A person who possesses a gene for an abnormal trait without showing signs of the disorder. The person may pass the abnormal gene on to offspring.

Chorionic villus sampling (CVS)—A procedure used for prenatal diagnosis at 10–12 weeks gestation. Under ultrasound guidance a needle is inserted either through the mother's vagina or abdominal wall and a sample of cells is collected from around the fetus. These cells are then tested for chromosome abnormalities or other genetic diseases.

Chromosome—A microscopic thread-like structure found within each cell of the body that consists of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Changes in either the total number of chromosomes or their shape and size (structure) may lead to physical or mental abnormalities.

Deoxyribonucleic acid (DNA)—The genetic material in cells that holds the inherited instructions for growth, development, and cellular functioning.

Desmopressin (DDAVP)—A drug used in the treatment of von Willebrand's disease.

Diagnostic testing—Testing performed to determine if someone is affected with a particular disease.

DNA testing—Analysis of DNA (the genetic component of cells) in order to determine changes in genes that may indicate a specific disorder.

Endothelial cells—The cells lining the inner walls of the blood vessels.

Factor VIII—A protein involved in blood clotting that requires VWF for stability and long-term survival in the bloodstream.

Gene—A building block of inheritance, which contains the instructions for the production of a particular protein, and is made up of a molecular sequence found on a section of DNA. Each gene is found on a precise location on a chromosome.

Mutation—A permanent change in the genetic material that may alter a trait or characteristic of an individual, or manifest as disease, and can be transmitted to offspring.

Platelets—Small disc-shaped structures that circulate in the bloodstream and participate in blood clotting.

Prenatal testing—Testing for a disease such as a genetic condition in an unborn baby.

Protein—Important building blocks of the body, composed of amino acids, involved in the formation of body structures and controlling the basic functions of the human body.

Skin hematoma—Blood from a broken blood vessel that has accumulated under the skin.

von Willebrand factor (VWF)—A protein found in the blood that is involved in the process of blood clotting.

genes are changed, which often leads to more severe symptoms. Type 1 VWD is called an autosomal dominant condition since it is caused by a change in only one *VWF* gene. Since type 1 VWD results in only a slight decrease in the amount of VWF produced, the symptoms are often mild and even nonexistent in some patients. Most cases of Type 2 VWD are autosomal dominant since they are caused by a change in only one *VWF* gene that results in the production of an abnormal protein. An autosomal dominant form of VWD can be inherited from either

parent or can occur spontaneously in the embryo that is formed when the egg and sperm cells come together during fertilization.

Some cases of type 2 VWD and all cases of type 3 VWD are autosomal recessive since they are caused by changes in both *VWF* genes. A person with an autosomal recessive form of VWD has inherited a changed gene from his or her mother and a changed gene from his or her father. Parents who have a child with an autosomal recessive form of VWD are called carriers, since they

each possess one changed *VWF* gene and one unchanged *VWF* gene. Many carriers for the autosomal recessive forms of type 2 VWD and type 3 VWD do not have any symptoms, although some people with type 3 VWD are born to parents who have type 1 VWD and may have symptoms. Each child born to parents who are both carriers for VWD has a 25% chance of having VWD, a 50% chance of being a carrier, and a 25% chance of being neither a carrier nor affected with VWD disease. A person with an autosomal dominant form of VWD has a 50% chance of passing the changed gene on to his or her children, who may or may not have symptoms.

Demographics

Approximately 1 out of 100 to 1 out of 10,000 people are affected with VWD, making it the most common inherited bleeding disorder (hemophilia). VWD affects people of all ethnic backgrounds. Approximately 70%–80% of people with VWD have type 1 and close to 20%–30% have type 2. Type 3 is very rare and occurs in less than one percent of people with VWD.

Signs and symptoms

VWD is usually a relatively mild disorder characterized by easy bruising, recurrent nosebleeds, heavy menstrual periods, and extended bleeding after surgeries and invasive dental work. There is a great deal of variability in the severity of symptoms, which can range from clinically insignificant to life threatening. Even people within the same family who are affected with the same type of VWD may exhibit different symptoms. An individual with VWD may exhibit a range of symptoms over the course of his or her lifetime and may experience an improvement in symptoms with age. The severity of the disease is partially related to the amount and type of VWF that the body produces, but is also influenced by other genetic and nongenetic factors.

Type 1

Type 1, the mildest form of VWD, is usually associated with easy bruising, recurrent nosebleeds, heavy menstrual periods, and prolonged bleeding after surgeries and invasive work. Many people with type 1 VWD do not have any noticeable symptoms or only have prolonged bleeding after surgery or significant trauma. The amount of VWF produced by the body increases during pregnancy, so prolonged bleeding during delivery is uncommon in people with type 1 VWD.

Type 2

People with type 2 VWD usually have symptoms from early childhood and symptoms may even be present

at birth. They usually experience prolonged bleeding from cuts, easy bruising, nosebleeds, skin hematomas, and prolonged bleeding from the gums following teeth extraction and minor trauma. More than 50% of women with type 2 VWD experience heavy periods that may require a blood transfusion. Gastrointestinal bleeding is rare but can be life-threatening. Some women with type 2 VWD exhibit prolonged bleeding during delivery.

Type 3

Type 3 VWD can be quite severe and is associated with bruising and bleeding from the mouth, nose, intestinal, and genital and urinary tracts. Type 3 is also associated with spontaneous bleeding into the muscles and joints, which can result in joint deformities. Some women with type 3 VWD experience prolonged bleeding during delivery.

Diagnosis

Diagnostic testing

Many people with VWD have mild symptoms or symptoms that can be confused with other bleeding disorders making it difficult to diagnose it on the basis of clinical symptoms. VWD should be suspected in any person with a normal number of platelets in their blood and bleeding from the mucous membranes such as the nose, gums, and gastrointestinal tract. Testing for an individual with suspected VWD often includes the measurement of:

- how long it takes for the bleeding to stop after a tiny cut is made in the skin (the bleeding time)
- the amount of VWF (VWF antigen measurement)
- the activity of VWF (ristocetin co-factor activity)
- the amount of factor VIII (factor VIII antigen measurement)
- activity of factor VIII

People with type 1 VWD usually have an increased bleeding time but they may have an intermittently normal bleeding time. They also have a decreased amount of VWF, decreased VWF activity, and usually have slightly decreased factor VIII levels and activity. People with type 2 VWD have a prolonged bleeding time, decreased activity of VWF, and may have decreased amounts of VWF and factor VIII, and decreased factor VIII activity. Type 3 individuals have undetectable amounts of VWF, negligible VWF activity, factor VIII levels of less than 5%–10%, and significantly reduced factor VIII activity. The activity of VWF is reduced for all types of VWD, making it the most sensitive means of identifying all three types of VWD. Patients with borderline results should be tested two to three times over a three-month period.

Once a patient is diagnosed with VWD, further testing such as VWF multimer analysis and ristocetin-

QUESTIONS TO ASK YOUR DOCTOR

- What are the risks and benefits of DDAVP therapy?
- In DDAVP therapy, do you recommend the intravenous or nasal inhaler mode of treatment?
- How can nasal and mouth bleeding be managed?
- In addition to aspirin, should other drugs be avoided?

induced platelet aggregation (RIPA) may need to be performed to determine the subtype. Multimer analysis evaluates the structure of the VWF, and RIPA measures how much ristocetin is required to cause the clumping of platelets in a blood sample. The VWF multimer analysis is able to differentiate people with a structurally normal VWF (type 1) from people with a structurally abnormal VWF (type 2), and is often able to identify the subtype of patients with type 2 VWD. People with type 1 VWD usually have normal to decreased RIPA concentrations. Depending on the subtype, patients with type 2 VWD either have increased or decreased RIPA. In people with type 3 VWD, RIPA is usually absent and the multimer analysis shows undetectable VWF.

In some cases DNA testing can be a valuable adjunct to biochemical testing. The detection of gene alteration(s) can confirm a diagnosis and can determine the type and subtype of VWD. It can also help to facilitate prenatal testing and testing of other family members. Unfortunately, many people with VWD possess DNA changes that are not detectable through DNA testing. A person who has a mother, father, or sibling diagnosed with VWD should undergo biochemical testing for VWD. If the relative with VWD possesses a detectable gene change, then DNA testing should also be considered.

Prenatal testing

If one parent has been diagnosed with an autosomal dominant form of VWD, or both parents are carriers for an autosomal recessive form of VWD, then prenatal testing can be considered. If the parent with an autosomal dominant form of VWD possesses a detectable gene change, or both parents who are carriers for an autosomal recessive form of VWD possess detectable mutations, then DNA testing of their fetus would be available. DNA testing can be performed through amniocentesis or chorionic villus sampling. If the DNA change in the

parent(s) is unknown then prenatal testing can sometimes be performed through biochemical testing of blood obtained from the fetal umbilical cord, which is less accurate and is associated with a higher risk of pregnancy loss.

Treatment and management

VWD is most commonly treated by replacement of VWF through the administration of blood products that contain VWF or through treatment with desmopressin (DDAVP, 1-deamino-8-D-arginine vasopressin). DDAVP functions by increasing the amount of factor VIII and VWF in the bloodstream. Treatment with blood products or DDAVP may be started in response to uncontrollable bleeding or may be administered prior to procedures such as surgeries or dental work. The type of treatment chosen depends on the type of VWD and a patient's response to a preliminary treatment trial.

Treatment with desmopressin

DDAVP is the most common treatment for people with type 1 VWD. About 80% of people with type 1 VWD respond to DDAVP therapy. Treatment with DDAVP can also be used to treat some people with type 2 VWD. Patients with Type 2B VWD should not be treated with this medication since DDAVP can induce dangerous platelet clumping. Type 3 VWD should not be treated with DDAVP since this medication does not increase the level of VWF in type 3 patients. DDAVP should only be used in people who have been shown to be responsive through a pre-treatment trial transfusion with this medication.

DDAVP can be administered intravenously or through a nasal inhaler. DDAVP has relatively few side effects, although some people may experience facial flushing, tingling sensations, and headaches after treatment with this medication. Often treatment with this medication is only required prior to invasive surgeries or dental procedures.

Treatment with blood products

Patients who are unable to tolerate or are unresponsive to drug-based treatments are treated with concentrated factor VIII obtained from blood products. Not all factor VIII concentrates can be used since some do not contain enough VWF. The concentrate is treated to kill most viruses, although caution should be used since not all types of viruses are destroyed. If the factor VIII concentrates are unable to manage a severe bleeding episode, then blood products called cryoprecipitates, which contain concentrated amounts of VWF, or platelet concentrates should be considered. Caution should be

used when treating with these blood products since they are not treated to kill viruses.

Recombinant VWF

As of 2013, patients who did not respond to treatments with desmopressin or other therapy methods could be treated using Recombinant VWF. Recombinant VWF is a protein replacement therapy and in clinical trials has shown very high efficacy in the treatment and management of musculoskeletal and mucosal bleeding.

Other treatments and precautions

Medications called fibrinolytic inhibitors can be helpful in the control of intestinal, mouth, and nose bleeding. Estrogens such as are found in oral contraceptives increase the synthesis of VWF and can sometimes be used in the long-term treatment of women with mild to moderate VWD. Estrogens are also sometimes used prior to surgery in women with type 1 VWD. Some topical agents are available to treat nose and mouth bleeds. Patients with VWD should avoid taking aspirin, which can increase their susceptibility to bleeding, and people with severe forms of VWD should avoid activities that increase their risk of injury such as contact sports.

Prognosis

The prognosis for VWD disease is generally fairly good and most individuals have a normal lifespan. The prognosis can depend, however, on accurate and early diagnosis and appropriate medical treatment.

Waardenburg syndrome

Definition

Waardenburg syndrome (WS) encompasses several different hereditary disorders, the main features of which variably include abnormal pigmentation, hearing loss, and a subtle difference in facial features. Certain other physical anomalies occur less frequently in WS.

Description

In 1951, Dr. Petrus Waardenburg reported a syndrome of dystopia canthorum, heterochromia of the irides, and hearing loss. Dystopia canthorum (also called telecanthus) describes a subtle, unusual facial feature in which the inner corners of the eyes (canthi) are spaced farther apart than normal, yet the eyes (pupils) themselves are normally spaced, resulting in eyes that appear to be widely spaced, even though they are not. Heterochromia means different-colored, and irides is the plural form of iris—the colored portion of the eye. Thus, someone with heterochromia of the irides has different colored eyes, often one brown and one blue. Another feature not originally noted by Dr. Waardenburg, but now considered a major sign of WS, is a white forelock (white patch of hair extending back from the front of the scalp). In fact, disturbances in pigmentation (coloring) of various parts of the body are consistent features of WS. Uncommon but serious physical anomalies associated with WS include Hirschsprung disease (intestinal malformation), spina bifida, cleft lip/palate, and musculoskeletal abnormalities of the arms.

Five types of WS have been defined based on clinical symptoms or genetic linkage. Six different genes are associated with WS. Most families show autosomal dominant inheritance, but autosomal recessive inheritance and sporadic (single) cases are also seen. People with WS are not at increased risk for intellectual disability and vision loss is not more common. For the majority of those with

WS, hearing loss is the only major medical problem they will have.

WS1 is the “classic” form of WS, and if someone uses just the name Waardenburg syndrome with no modifying number, they are most likely referring to the group of disorders as a whole or just WS1. WS2 may occasionally be referred to as WS without dystopia canthorum. WS3 is also known as Klein-Waardenburg syndrome, as well as WS with upper limb anomalies. Alternate names for WS4 include Waardenburg-Hirschsprung disease, Waardenburg-Shah syndrome, Shah-Waardenburg syndrome, and Hirschsprung disease with pigmentary anomaly.

Genetic profile

Since Dr. Waardenburg’s original description of his patients in 1951, many more families with the same or similar symptoms have been reported. By 1971, it became clear that a proportion of families have WS without dystopia canthorum. At that time, Waardenburg syndrome was divided into two distinct types: WS1 and WS2. In addition, a few individuals with typical signs of WS1 were found to also have musculoskeletal symptoms. This form of the disorder was named Klein-Waardenburg syndrome, now also known as WS3. Further, some researchers noted yet a different pattern of anomalies involving pigmentation defects and Hirschsprung disease, which eventually became known as WS4. Finally, genetic testing of WS2 families has shown at least two subtypes—those that show genetic linkage are designated as WS2A and WS2B.

The four major types of WS have all been studied through DNA (genetic) analysis. There is some agreement between the clinical subtypes of WS and mutations in different genes, but genetic analysis has also served to confuse the naming scheme somewhat.

WS1

A number of different mutations in a single copy of the *PAX3* gene on chromosome 2 are responsible for all

Waardenburg Syndrome					
Type	Inheritance	Gene	Chromosome	Demographics	Symptoms
WS 1	AD	PAX3	2	1 in 40,000 for all types; WS 3 and WS 4 are less common than WS 1 and WS 2	Dystopia canthorum (99%); Medial flare of eyebrow or joining of eyebrows in the middle (70%); Hypopigmentation of skin, hair, and/or irides; Heterochromia of irides (30%); Hearing loss (60%)
WS 2A	AD	MITF	3		Same symptoms as WS 1, but without dystopia canthorum; Incidence of symptoms varies from WS 1, e.g. hearing loss (80%), heterochromia of irides (50%), joining of eyebrows (5%)
WS 2B	AD	"WS2B"	1		See WS 2A
WS 3	AD or sporadic	Deletions including PAX3	2		Similar symptoms to WS 1 but also features abnormalities of arm muscles and bones
WS 4	AR AR AD	EDNRB EDN3 SOX10	13 20 22		Usually dystopia canthorum is absent and incidence of hearing loss is reduced; Hirschsprung disease

(Gale)

cases of WS1, meaning it is always inherited as an autosomal dominant trait. The *PAX3* gene plays a role in regulating other genes that have some function in producing melanocytes, which are pigment-producing cells. *PAX3* was formerly known as the *HUP2* gene.

WS2A

People that have typical signs of WS2 are designated as having WS2A only if genetic testing shows them to have a mutation in the *MITF* gene on chromosome 3. As with WS1, all cases of WS2A appear to be autosomal dominant. There is evidence that *MITF* is one of the genes regulated by *PAX3*.

WS2B

Some individuals with typical WS2 have had normal *MITF* gene analysis. A search for a different WS2 gene showed that some cases are linked to a gene on chromosome 1. This gene has been tentatively designated WS2B until its exact chromosomal location and protein product are identified. WS2B displays autosomal dominant inheritance.

WS3

Several people with a severe form of WS1 have been shown by genetic analysis to have a deletion of a small section of chromosome 2. Several genes are located in this section, including the *PAX3* gene. Not all patients with WS3 have had the exact same genetic anomaly on chromosome 2, which may explain the variation in symptoms that have been reported. Some families with WS3 have displayed autosomal dominant inheritance,

while other individuals with the condition have been sporadic cases.

WS4

Mutations in three different genes—*EDNRB*, *EDN3*, and *SOX10* on chromosomes 13, 20, and 22, respectively—have been linked to WS4. Those cases of WS4 associated with *EDNRB* and *EDN3* show autosomal recessive inheritance, while the *SOX10*-associated cases are dominantly inherited.

Individuals with one of the autosomal dominant types of WS have a 50% risk of passing on the gene each time they have a child. A couple that has a child with WS4 linked to *EDNRB* or *EDN3* faces a 25% risk for recurrence in each subsequent child. WS is quite variable, even within families. For instance, a parent with minimal pigment disturbance, mild facial features, and no hearing loss may have a child with pronounced physical features and deafness, and vice versa. There may be some correlation between specific gene mutations and the incidence of certain symptoms, but precise predictions are not possible.

The six genes listed are those known to be associated with WS. It is expected, however, that more genes will be identified, especially since only a minority of WS2 cases have shown linkage to the *MITF* and WS2B genes.

Demographics

The prevalence of WS is estimated at 1 in 40,000. About 3% of all children with congenital deafness have WS. WS1 and WS2 occur with approximately the same frequency. WS3 and WS4 are much less common than

KEY TERMS

Dystopia canthorum—A wide spacing between the inner corners of the eyes, with the eyes themselves having normal spacing. Also called telecanthus.

Heterochromia irides—A medical term for individuals with different-colored eyes.

Hirschsprung disease—A deformation in which the colon becomes enlarged (megacolon) due to abnormal nerve control of that portion of the large intestine.

Hypopigmentation—Decreased or absent color (pigment) in a tissue.

Neural crest cells—A group of cells in the early embryo, located on either side of the area that will eventually develop into the spinal cord. The cells migrate (move) away from the area and give rise to various body structures, including melanocytes (pigment producing cells), certain structures of the face and head, and parts of the nervous system.

Neurocristopathy—A disorder that results from abnormal development and/or migration of the neural crest cells in the embryo.

Sensorineural—Type of hearing loss due to a defect in the inner ear (sensing organ) and/or the acoustic nerve.

Synophrys—A feature in which the eyebrows join in the middle. Also called blepharophimosis.

the other types. The majority of people with WS are Caucasian, but members of other ethnic groups may be affected as well.

Signs and symptoms

WS1

Dystopia canthorum is seen in 99% of people with WS1. Other facial features may include decreased length of the nasal bone, a broad/high nasal root (top of the nose), and increased length of the lower face. Seventy percent of people with WS1 have either a medial flare of the eyebrows or synophrys.

Some type of pigmentary disturbance is nearly always present and involves hypopigmentation of the skin, hair, and/or irides. Unlike the more common forms of albinism that often involve a generalized lack of pigment in the body, WS is characterized by patches of hypopigmentation—often termed “partial albinism.” A white forelock or premature graying is seen in about

70% of people with WS1. The eyelashes and patches of body hair may also be hypopigmented. Heterochromia of the irides may be complete (25% of patients) or partial (5% of patients). In complete heterochromia, each eye is a different color. In partial heterochromia, an individual iris in one or both eyes is composed of two colors. Those people with WS1 who do not have iris heterochromia often have brilliant blue coloring of both eyes.

Although estimates vary, hearing loss of some type is present in about 60% of individuals with WS1. The true prevalence is difficult to determine because of the variable nature of the condition. About 80% of those with hearing loss are affected in both ears (bilateral). Profound hearing loss occurs in some 25% of all people diagnosed with WS1.

Spina bifida is seen in a very small percentage of newborns with WS1, as is cleft lip/palate. Hirschsprung disease, a deformation in which the colon becomes enlarged, is a somewhat more frequent anomaly. Sprengel anomaly (elevated shoulder blade) can also be seen. Overall, about 10% of children with WS1 have one of these anomalies.

WS2

The major clinical distinction between WS1 and WS2 is the absence of dystopia canthorum in WS2. Otherwise the conditions mostly differ by incidences of the various symptoms. The incidence of hearing loss in WS2 is 80%, with about 30% having a profound loss. Heterochromia of the irides occurs in 50% of patients. White forelock, premature graying, and hypopigmented skin patches are each found in about 15%–20% of people with WS2. Synophrys occurs in only 5% of patients.

WS3

WS3 could be considered a subtype of WS1 since both are associated with the *PAX3* gene. The distinction is clinical, with the added feature in WS3 being abnormalities of the muscles and bones of the arms. Some cases of WS3 have been sporadic; several individuals diagnosed with WS3 have been in families where other members have typical signs of WS1. Thus, in some cases, WS3 can be considered a severe form of *PAX3*-associated WS and is a dramatic example of the variability that can occur within families.

WS4

Individuals with WS4 usually do not have dystopia canthorum, and often do not have hearing loss. Hirschsprung disease is the major distinguishing feature of WS4. In fact, individuals who carry a single abnormal *EDNRB* or *EDN3* gene, as opposed to two abnormal copies of

either gene in WS4 have only Hirschsprung disease. A small proportion of people with WS4 have been found to have an abnormal *SOX10* gene.

Diagnosis

In the early 1990s, a group of researchers known as the Waardenburg Consortium established criteria for diagnosing someone with WS1. They considered the major criteria of WS1 to be:

- congenital sensorineural hearing loss not due to some other obvious cause
- pigmentary disturbance of the iris
- hair hypopigmentation of some type
- dystopia canthorum
- an affected first-degree relative (parent, sibling, or child)

Minor criteria established by the Waardenburg consortium include:

- several areas of hypopigmented skin
- synophrys or medial flare of the eyebrows
- broad and high nasal root
- hypoplastic alae nasi (cartilage and skin around the nostrils)
- premature graying of hair

In order to be diagnosed with WS1, a person must have two major criteria, or one major plus two minor criteria. A modification of the list for WS2 includes removing dystopia canthorum, and including premature graying as a major criterion. With those modifications, a person with no family history of the condition should have two major criteria to be considered for WS2, and someone with an affected family member need only have one major criterion. Diagnosing WS2 can be more difficult than diagnosing WS1 because of the lack of dystopia canthorum. In addition, some people with a white forelock or premature graying may color their hair, and thus conceal an important sign.

As indicated, the distinction between WS1 and WS3 is clinical, with musculoskeletal anomalies added to the list of criteria for WS1. The criteria for diagnosing WS4 would be similar to those for WS2, with the inclusion of Hirschsprung disease as a major criterion, and the probable exclusion of dystopia canthorum, broad nasal root, and severe hearing loss. In addition, by definition WS4 is not linked to *PAX3*, *MITF*, or *WS2B*, and is linked to one of the established WS4 genes (assuming genetic testing is available and informative).

QUESTIONS TO ASK YOUR DOCTOR

- At what point should my baby be evaluated for hearing loss?
- Which family members should undergo genetic testing?
- If I have WS, when should my child be screened for Hirschsprung disease?
- Do you recommend any orthopedic treatments?

Treatment and management

The primary medical consideration for people with WS is hearing loss. The most effective intervention is hearing aids. It is widely accepted that infants at risk for hearing loss, such as those who may inherit WS from a parent, can benefit from screening in the newborn period. An undiagnosed hearing deficit can result in delays in speech and learning. Children with profound hearing loss are eligible for special accommodations in their education, and the entire family can benefit by starting to use sign language very early.

Although spina bifida in WS is uncommon, the potential complications are serious. Infants with spina bifida usually have damage to the spinal cord at the level of the open spine and consequently have either partial or total paralysis below that point. The opening in the spine can be repaired, but the neurological damage to the spinal cord is permanent. Cleft lip/palate is also uncommon in WS and can be a serious birth defect. Children with cleft lip/palate usually require several surgeries, but the outcome of the repair is generally very good. It would be prudent to screen any infant of a parent with WS for Hirschsprung disease. Surgical removal or repair of the affected segment of colon is often necessary. Depending on the severity of the musculoskeletal anomalies, a child with WS3 might require some sort of orthopedic intervention, such as casting, bracing, or surgery. A few children with WS3 have had only minor joint contractures of the arms and hands.

Genetic counseling is beneficial for any family with WS. Prenatal diagnosis might be an option if genetic testing in the family is informative, but many couples may not choose invasive testing if they would not terminate a pregnancy for WS.

Prognosis

The majority of people with WS lead productive lives. In the absence of severe hearing loss, many people

with WS would not be noticed as having a condition by anyone in the general population. If hearing loss is present, it usually does not get worse and is often amenable to treatment. There is little hope for any preventive measures for WS since all of the features of the syndrome occur early in embryonic development and are present at birth.

Walker-Warburg syndrome

Definition

Walker-Warburg syndrome (WWS) is a congenital disorder of the central nervous system involving fatal neurological lesions. There are multiple malformations of the brain,

KEY TERMS

Agyri—A lack of convolutions or normal folds in the brain tissue.

Encephalocele—A gap in the skull through which membranes and brain tissue may protrude.

Hydrocephalus—The excess accumulation of cerebrospinal fluid around the brain, often causing enlargement of the head.

Retina—The light-sensitive layer of tissue in the back of the eye that receives and transmits visual signals to the brain through the optic nerve.

Retinal dysplasia—Improper development of the retina that can lead to detachment of the retina.

eyes, and muscle tissue that distinguish WWS from similar malformation syndromes. It is also known by the acronym HARD +/- E syndrome (hydrocephalus, agyri, retinal dysplasia, plus or minus "e" for encephalocele).

Description

Individuals affected by WWS typically show a combination of severe brain, eye, and muscle defects. Multiple malformations of the brain include type II lissencephaly, a condition in which the brain lacks normal convolutions and is unusually smooth without folds. Eighty-four percent of the infants with WWS have macrocephaly (an enlarged head). In half of these cases the macrocephaly is apparent at birth, and in a quarter of the cases it develops postnatally. Hydrocephalus, or excessive accumulation of cerebrospinal fluid around the brain, occurs in 95% of infants with WWS. This fluid fills abnormally large ventricles or spaces in the brain. Fifty percent of affected infants have an encephalocele, or gap in the skull that does not seal. The meninges or membranes that cover the brain may protrude through this gap. The formation of an encephalocele may be associated with the failure of the neural tube to close during development of the fetus. A malformed cerebellum characterizes the syndrome as well as distinct muscle abnormalities, including congenital muscular dystrophy.

Ocular defects occur in 100% of infants with WWS. The most common are abnormally small eyes and retinal abnormalities, which arise from the improper development of the light sensitive area at the back of the eye. Cataracts may also be present, and more than three quarters of the infants born with WWS have a defect in the anterior chamber of the eye. WWS syndrome leads to severely delayed mental development and is often lethal in infancy.

QUESTIONS TO ASK YOUR DOCTOR

- What supportive measures do you recommend for children born with WWS?
- At what point should seizures be controlled medically?
- What are the risks and benefits of shunting?
- Which family members should undergo genetic testing?
- If WWS runs in my family, what are the chances that I will have a child affected by WWS?

Genetic profile

WWS is inherited in an autosomal recessive pattern. Offspring of parents who have had one affected infant have a 25% chance of having another child with WWS. The locations of the causative genes remain unknown.

Demographics

WWS is extremely rare. Cases described in the literature cite siblings with WWS born to consanguineous (closely related) parents as well as cases in families not known to be at risk.

Signs and symptoms

Clinical signs include a malformed head, small eyes, cataracts, retinal abnormalities, and muscle weakness. An encephalocele may be present as well. Microscopic examination reveals that the cells and tissues of the brain develop in a highly disorganized fashion. Seizures may occur in affected individuals.

Diagnosis

Prenatal ultrasound can reveal some of the brain anomalies associated with WWS; most commonly, hydrocephalus and encephalocele. Lissencephaly cannot be diagnosed prenatally as normal fetal brains appear smooth. After birth, diagnosis is made on the basis of physical features and ultrasound exams. MRI may be used to confirm the smooth brain feature or type II lissencephaly typical of WWS. Genetic analysis can also help distinguish WWS from Fukuyama-type congenital muscular dystrophy (FCMD), which has several similar features. WWS can be differentiated from other syndromes that display hydrocephalus or encephalocele by the presence of eye abnormalities including retinal defects, cataracts, and anterior

chamber defects. Genetic testing for Fukuyama-type congenital muscular dystrophy distinguishes these symptoms from WWS.

Treatment and management

The severe malformations of the brain are untreatable and many infants with WWS die within the first year of life. Supportive care is required to provide comfort and nursing needs. Seizures may be controlled with medication and shunting may be required to control the swelling effects of hydrocephalus. A shunt or short plastic tube can be placed to divert the excess cerebral spinal fluid to another area of the body where it can ultimately be absorbed.

Genetic counseling is recommended for families at risk.

Prognosis

Patients have a very limited life expectancy and the syndrome is generally considered lethal. Most patients die before the age of two.

Ward-Romano syndrome see **Long QT syndrome**

Weaver-Williams syndrome see **Weaver syndrome**

Weaver syndrome

Definition

Weaver syndrome is a congenital genetic syndrome associated with rapid growth beginning in the prenatal period, as well as with a specific facial appearance and certain skeletal features. It has also been referred to as Weaver-Williams syndrome.

Description

Weaver syndrome was first described by Dr. David Weaver in 1974. A number of different symptoms occur in Weaver syndrome. However, it primarily results in rapid growth beginning in the prenatal period and continuing through the toddler years and into the elementary school years. It is also strongly associated with the bones developing and maturing more quickly (advanced bone age), a distinctive appearing face, and developmental delay. Babies often have a hoarse, low-pitched cry.

Genetic profile

Weaver syndrome is caused by mutation in the *EZH2* gene and, in rare cases, the *NSD1* gene. The *EZH2* gene provides instructions for making a type of enzyme called histone methyltransferase that modifies proteins (histones) that help DNA give chromosomes their shape. The *EZH2* enzyme is part of a protein group called the polycomb repressive complex-2. This complex turns off individual genes involved in the process of cell differentiation (the process that determines the type of cell an immature cell will become). Mutations in the *EZH2* enzyme may disrupt a process called methylation (an essential process by which genes are activated and deactivated) and affect many organs and tissues, resulting in the symptoms of Weaver syndrome.

The *NSD1* gene is involved in production of a protein that is not fully understood. Researchers suspect that this protein is involved in the genetic component of normal growth and development. Abnormalities in this

protein may cause growth to accelerate. Individuals with mutations in the *NSD1* gene have been diagnosed with Weaver syndrome, but researchers believe they should be diagnosed with Sotos syndrome (which is also characterized by rapid and accelerated growth) instead, since it is caused by mutations of this gene.

Weaver syndrome is, for the most part, a sporadic condition, which means that a child affected by it did not inherit it from a parent. In a very few families, autosomal dominant inheritance has been reported, which means that both a parent and his/her child is affected by Weaver syndrome. The exact cause of Weaver syndrome is not fully understood. Symptoms of Weaver syndrome are sometimes confused with Sotos syndrome.

Demographics

Weaver syndrome is rare; only about 30 to 50 cases have been published in the medical literature. It occurs in both males and females.

Seventeen-year-old Rumeysa Gelgi has Weaver syndrome, which has led to her 2.13-meter height (about 6 feet, 11 inches). (Ibrahim Yozoglu/Anadolu Agency/Getty Images)

Signs and symptoms

Children with Weaver syndrome tend to have large heads. The faces of children with Weaver syndrome are usually very similar to each other, more so than to other family members, and include a round face, small chin, long philtrum (groove in the midline of the upper lip), large ears, and eyes that are farther apart from each other than usual. Other common symptoms include hypertonia (increased muscle tone, tight muscles) as well as hypotonia (decreased muscle tone, “floppy” muscles) and a hoarse, low-pitched cry in babies.

The excessive prenatal growth often results in the newborn being large with respect to weight, length, and head circumference. The rapid growth continues through the toddler and youth years with the child’s length and height often being above the 97th percentile, meaning that out of 100 children of the same age, the child is longer/taller than 97 of the children. There is very limited information on the rate of growth through adolescence and on final height, as most of the patients diagnosed with Weaver syndrome who have been reported in the medical literature have been children. In addition, given that the condition was first described 25 years ago, long-term clinical information is just becoming available.

There are a number of other features that have been associated with Weaver syndrome. The child may have difficulty extending elbows and knees completely, fingers and/or toes may be permanently flexed (camptodactyly) or have other problems such as overlapping fingers/toes or clubfoot, and the skin may appear loose. The child may have normal or delayed development; severe intellectual impairment is rarely seen. Speech may be delayed, and when present, may be slurred. A child with Weaver syndrome may also have behavioral problems such as poor concentration; temper tantrums, which may be related to frustrations arising from communication problems; and obsessive and repetitive patterns of play.

Diagnosis

Diagnosis of Weaver syndrome is based solely upon clinical examination, medical history, and x-ray data. There are no laboratory tests that can provide a diagnosis. The clinical criteria that are considered to be diagnostic for Weaver syndrome are excessive growth beginning in the prenatal and infancy period, a characteristic facial appearance, advanced bone age with the bones in the wrist being more advanced than other skeletal bones, metaphyseal flaring in the leg bones (the ends of the bone are wider than normal), and developmental delay.

There are many conditions and genetic syndromes that cause excessive growth; consequently, a baby and/or child who has accelerated growth needs to be

KEY TERMS

Advanced bone age—The bones, on x-ray, appear to be those of an older individual.

Congenital—Refers to a disorder that is present at birth.

Developmental milestones—Infants and toddlers develop skills at certain ages. For example, by nine months, a child should be able to grasp and toss a bottle.

Karyotype—A standard arrangement of photographic or computer-generated images of chromosome pairs from a cell in ascending numerical order, from largest to smallest.

Metaphyseal flaring—A characteristic found only by x-rays. If present, it means that the ends of the bone are wider than normal.

thoroughly examined by a physician knowledgeable in overgrowth and genetic syndromes. The evaluation includes asking about health problems in the family as well as asking about the growth patterns of the parents and their final height. In some families, growth patterns are different and thus may account for the child’s excessive growth. The child will also undergo a complete physical examination. The child will also be examined in terms of his/her facial appearance, with special attention paid to the shape of his/her head, width of the face at the level of the eyes, and appearance of the chin and forehead. Besides measurement of the head circumference, arm length, leg length, and wing span will also be measured. Laboratory testing may also be done. A chromosome analysis (karyotype) may be performed as well as testing for another genetic syndrome called fragile-X syndrome. The patient’s bone age should also be assessed. Bone age is determined by x-rays of the hand. It is known that a child’s age can be predicted by the appearance of the wrist bones. In some cases the bones may develop or mature more quickly than normal, or in other words, the child’s wrist bones appear to be those of an older child. This is referred to as advanced bone age. Advanced bone age is present in nearly every child with Weaver syndrome. It does not appear to result in other health problems. If the child begins to lose developmental milestones or appears to stop developing, metabolic testing may be done to evaluate for a metabolic condition called Sanfilippo syndrome. Developmental milestones refer to the skills infants and toddlers acquire as they get older, such as smiling, cooing, grasping toys, rolling over, walking, and talking.

QUESTIONS TO ASK YOUR DOCTOR

- What are the risks and benefits of surgery?
- Do you recommend physical, occupational, or speech therapy?
- Is a behavioral assessment recommended?
- What developmental milestones should I look for in my baby?

Treatment and management

There is no cure for Weaver syndrome. However, the symptoms that cause problems can be treated and managed. Surgery may be used to correct any skeletal problems such as clubfoot or finger or toe problems. Physical and occupational therapy may help with muscle tone. Speech therapy may help with speech, and behavioral assessments and treatments may help with behavioral problems.

Prognosis

With appropriate treatment and management, children with Weaver syndrome appear to do well. Intellectually, most individuals with Weaver syndrome are normal. Weaver syndrome is not associated with a shortened lifespan.

Weissenbacher-Zweymuller syndrome

Definition

Weissenbacher-Zweymuller syndrome (WZS) is a genetic form of dwarfism in which affected individuals are born with small, underdeveloped jaws (micrognathia), cleft palate, short arms and legs (rhizomelia), dumbbell-shaped arm and leg bones, protruding wide-spaced eyes (hypertelorism), and incompletely formed back bones (vertebral coronal clefts). Unlike most other forms of dwarfism, individuals affected by Weissenbacher-Zweymuller start out being affected by dwarfism and then have a period of gradual growth and bone change that leads to normal physical development by five or six years of age.

Description

Weissenbacher-Zweymuller syndrome refers to a rare disorder of small underdeveloped jaws (micrognathia), delayed bone growth, and unusual bone formation first described in 1964 by Weissenbacher and Zweymuller. The formation of bones is delayed because an important structural component of bone called cartilage does not form correctly. Since bone development is delayed, early milestones like walking and physical growth are delayed. Due to cleft palate, many individuals affected by WZS have speech and language delays. In most cases, physical, motor, mental, and academic development is normal by five or six years of age. Alternate names sometimes used for WZS include Pierre Robin syndrome with fetal chondrodysplasia and heterozygous otospondylomegaepiphyseal dysplasia (OSMED).

Genetic profile

Weissenbacher-Zweymuller syndrome appears to be caused by a single change or mutation in a gene called *COL11A2* located on the short arm of chromosome 6. The mutation in *COL11A2* leads to the incorrect formation of collagen. Since collagen is an important structural part of cartilage and bone, a mutation in *COL11A2* leads to the signs and symptoms of WZS. The specific mutation that leads to WZS is inherited in an autosomal

recessive pattern. An autosomal recessive condition is caused by the inheritance of two abnormal copies of a gene.

In the 1970s and 1980s, there was some confusion among geneticists who were uncertain if WZS is a separate syndrome or part of another genetic syndrome. Although this confusion is not completely resolved, in 1993 an important study compared WZS to other related genetic syndromes and concluded that WZS is a separate genetic disorder that should not be “lumped” into the category of other genetic syndromes like Stickler syndrome. Since that study, a 1998 genetic study found that WZS and another syndrome called otospondylomegaepiphyseal dysplasia (OSMED) appear to be caused by different mutations in the same gene. This finding led the authors to suggest that the term “OSMED” be used to encompass a broad category that includes WZS as “heterozygous” OSMED while the other syndrome now called OSMED should be called “homozygous” OSMED. Because it has been found that WZS results from both heterozygous and homozygous mutations, researchers have suggested that this disorder follows both autosomal dominant and autosomal recessive inheritance patterns.

Demographics

WZS is a very rare disorder. The ethnic origin of individuals affected by WZS is varied and is not specific to any one country or ethnic population.

Signs and symptoms

Signs and symptoms of Weissenbacher-Zweymuller syndrome include: short arms and legs (rhizomelia), short stature at birth, an underdeveloped jaw (micrognathia), cleft palate, widely spaced eyes (hypertelorism), protruding eyes, a “snub” nose (depressed nasal bridge), dumb-bell shaped long leg and arm bones (widening of the metaphyses of long bones), and incompletely formed back bones (coronal cleft of the lumbar vertebrae). The most unique sign of WZS is the gradual improvement of these changes.

Diagnosis

Diagnosis of Weissenbacher-Zweymuller syndrome is usually made from physical examination by a medical geneticist and x-rays of the legs, arms, and back. Careful charts of growth and development over time also help with diagnosis. Most characteristic of WZS is the gradual improvement in bone size, growth, and shape.

Prenatal diagnosis of WZS is difficult, but can sometimes be made through a level II ultrasound examination of bone growth in the late second to third trimester of pregnancy. Genetic testing may be available through an

KEY TERMS

Autosomal dominant—A pattern of genetic inheritance where only one abnormal gene is needed to display the trait or disease.

Autosomal recessive—A pattern of genetic inheritance where two abnormal genes are needed to display the trait or disease.

Micrognathia—A term used to describe a small, underdeveloped lower jaw and chin.

Rhizomelia—A term used to describe the physical growth difference of short arms and legs.

Syndrome—A group of signs and symptoms that collectively characterize a disease or disorder.

amniocentesis procedure if the exact mutations running in the family are known. Genetic testing is done on a research basis in most cases.

One of the most important aspects in the diagnosis of WZS is ruling out other diagnoses. Conditions can be eliminated based on features that are not seen in WZS or are missing in other syndromes. For example, other conditions that look like WZS usually have progressively worsening symptoms instead of WZS’s characteristic catch-up growth. Additionally, most conditions resembling WZS are inherited in an autosomal dominant pattern through the family. In an autosomal dominant condition, only one copy of the gene for a particular condition is necessary for a person to experience symptoms of the condition. If a parent has an autosomal dominant condition, there is a 50/50 chance for each child to have the same or similar condition.

Conditions to rule out in differential diagnosis include:

- Stickler syndrome, in which affected individuals have eye problems and do not have short arms and legs at birth.
- Kniest dysplasia, in which affected individuals do not have an underdeveloped jaw, but they do have eye abnormalities.
- Marshall syndrome, in which affected individuals have hearing and eye abnormalities, but do not have short limbs at birth.
- Isolated Pierre-Robin sequence, in which individuals have an underdeveloped jaw and cleft palate alone without short arms and legs.
- Diastrophic dwarfism, in which affected individuals often have club feet, joint contractures, hypermobile thumbs, and non-bulbous bones.

QUESTIONS TO ASK YOUR DOCTOR

- How often should my baby have hearing, vision, and growth monitored?
 - Do you recommend physical, occupational, or speech therapy?
 - What developmental milestones should I watch for in my child?
 - Is there anything we can do during the preschool years in order to monitor intellectual development?
- Metatropic dwarfism, which is characterized by visible changes of the trunk and short limbs as the spine flattens and the bones become progressively deformed.
 - Traditional oto-spondylo-megaepiphyseal dysplasia (OSMED), which includes individuals affected by deafness and abnormal growth and development of the spine and growth plates at the end of the long bones (spondyloepiphyseal dysplasia) with large growth plates at the end of the long bones (epiphyses).

In conclusion, it is important to do a thorough and long-term physical examination, a family history, and a test for growth, hearing, and eyesight before making a diagnosis of WZS.

Treatment and management

The symptoms of WZS can be treated through follow-up and careful evaluation by a pediatric medical geneticist during the first years of life. Especially important to check are eyesight, hearing, and growth. Specific craniofacial clinics can help individuals affected by cleft palate with surgery, speech, and other related issues. Physical, occupational, speech, and language therapy may be suggested to help reduce “catch-up” time and developmental delays. As with any other disorder that includes developmental delays, specialists providing physical and language therapy can assist in the decision on whether special classes may help an individual child develop academically.

Prognosis

The chance for an individual affected by WZS to have normal physical, motor, mental, and school development by age six or seven is very good. To help in this development, early intervention with physical, occupational, speech, and language therapy and special classes may be helpful. A detailed case report in 1991 noted that

the intelligence of children with WZS is generally within normal range, though they may have mild-to-moderate intellectual delay in the preschool period. The same report notes that physical growth should be normal by age five or six.

Werner syndrome

Definition

Werner syndrome is a very rare, inherited disease that resembles premature aging. Since the gene responsible was discovered in the mid-1990s, Werner syndrome has greatly interested researchers as a possible model for the study of human aging. It is also being extensively studied for insights it may eventually supply into a number of other diseases, including cancer, diabetes mellitus, and atherosclerosis.

Description

This syndrome is named for the German physician C. W. Otto Werner (1879–1936). Werner was a medical

student in 1903 when he first observed the syndrome in four siblings, all about 30 years of age. The following year, Werner wrote about these observations in his “Inaugural Dissertation.”

The clinical signs and symptoms of Werner syndrome start to appear during the teen or early adult years, after which patients appear to age rapidly and have a greater-than-usual chance of developing cancer, cardiovascular disease, or diabetes mellitus. By the time the patient is 30–40 years old, he or she has the look of old age. The most common cause of death is heart attack.

While in many ways the signs and symptoms of Werner syndrome resemble those of premature aging (referred to in adults as progeria), there are also some significant differences. For instance, the tumors commonly seen in Werner syndrome patients are commonly derived from the cells of the mesoderm, a middle layer of the embryo that gives rise to a variety of tissues including cartilage, muscle, bone, kidneys, and connective tissue. In normal aging, tumors are more likely to be derived from the epithelial cells that cover the body’s exterior and line most of its hollow structures. Osteoporosis and soft-tissue calcium deposits are found both in Werner syndrome and normal aging, but the distribution of these conditions within the body is different in patients with Werner syndrome. In addition, patients with Werner syndrome do not generally experience symptoms of Alzheimer’s disease or premature cognitive decline, as do their aging counterparts in the general population.

Researchers are uncertain whether the symptoms of Werner syndrome are really a speeding-up of normal aging, or whether the many similarities are coincidental. There is nonetheless considerable optimism that further research into Werner syndrome may lead to a better understanding of aging, cancer, diabetes, systemic sclerosis, atherosclerosis, cataracts, and other conditions.

Genetic profile

Werner syndrome results from mutation of a single gene. In 1992, the gene responsible (*WRN*) was mapped to chromosome 8p11-12. In 1996, a research group based in Seattle cloned the *WRN* gene. It was also discovered that the syndrome resulted from an autosomal recessive mutation that affects a member of a family of enzymes known as helicases that unwind deoxyribonucleic acid (DNA) and, in some cases, ribonucleic acid (RNA).

Despite the discovery that Werner syndrome is caused by a genetic defect, researchers are unable to explain exactly how this defect causes the disease. The purpose of helicases in the body is not fully understood, but they are known to unwind DNA, splitting the double-stranded molecules into separate single-stranded

KEY TERMS

Atherosclerosis—Hardening of the arteries caused by cholesterol and fat deposits. Increases risk of heart disease, stroke, and other complications.

Progeria—Genetic abnormality that presents initially as premature aging and failure to thrive in children.

Systemic sclerosis—A rare disorder that causes thickening and scarring of multiple organ systems.

molecules. In this way, the enzymes are involved in the repair, recombination, replication, and transcription of DNA. There appear to be many damaged sites in DNA taken from patients with Werner syndrome. It has therefore been suggested that Werner syndrome may be caused by failure in these DNA-related processes, and that the somatic cells of those with Werner syndrome may be particularly prone to mutations.

The *WRN* gene is not known to bind to DNA damage, but recent research has suggested it might be able to sense the presence of damaged DNA. Since the discovery of the *WRN* gene, more than ten mutations have been uncovered. Many of these mutations were in the Japanese population. It has been suggested that the relatively high incidence of Werner syndrome in that country may be related to traditions of marriages between closely related individuals in some areas of Japan.

Researchers are still seeking to further study Werner syndrome and the *WRN* gene. Specifically, they hope to create mice with a genetic equivalent of the *WRN* gene, and to determine whether these mice would age more quickly than normal mice.

Demographics

Because of the limited number of cases, the demographic distribution of Werner syndrome is difficult to determine. Estimates of the number of people affected range from 1 in 95,000 to 1 in 1,000,000 people. Unlike progeria, which can be diagnosed at birth or soon after, Werner syndrome is not usually detected prior to adolescence. It is commonly noticed only after patients have failed to undergo the normal growth spurt associated with their teen years. The full range of symptoms is not usually seen until patients reach their 20s or 30s. Werner syndrome is more common in families in which a close biological relationship exists between parents. It occurs equally in both sexes. There is no evidence of a birth-order effect.

Signs and symptoms

The cardinal signs and symptoms of Werner syndrome start to appear after the age of ten. They are:

- Cataracts. These occur in both eyes, and usually develop by age 25 or 30.
- Skin problems including tight, shiny, smooth skin; ulceration; general wasting of the skin and localized wasting of the subcutaneous area underneath it; pigmentary changes; a thickening of the horny outer layer of the skin; and a characteristic bird-like facial appearance, including a beaked or pinched nose and unusually prominent eyes.
- Shortness of stature.
- An affected sibling or a close biological relationship between parents (third cousin or closer).
- Earlier-than-usual graying and/or thinning of scalp hair, usually by age 20.
- Excess amounts of hyaluronic acid (more commonly found in the body's connective tissues and in the fluids of the eyes and joints) in the urine.

Additional signs and symptoms of Werner syndrome include the following:

- Diabetes mellitus. This is usually mild, but can be found in between 44% and 67% of Werner syndrome patients.
- Impaired function of the ovaries or testes, as indicated by small or poorly developed genitalia or reduced fertility.
- Osteoporosis, most commonly in the upper limbs and spine, as well as in the lower limbs, feet, and ankles. In patients with Werner syndrome, osteoporosis is unlikely to be found in the skull or the torso.
- Unusually high bone density in the extremities of the finger and toe bones. This must be established by an x-ray examination.
- Deposits of calcium salts in soft tissues of the body. Common locations are around the Achilles tendon and the tendons of the elbow and the knee.
- Evidence pointing to earlier-than-usual arterial disease, such as a prior heart attack or abnormal electrocardiograms, etc.
- Rare or multiple tumors, or tumors derived from the mesoderm, the middle layer of the embryo. Werner syndrome is not marked by increased occurrence of all forms of tumors, but by selectively higher proportions of certain cancers that are relatively rare.
- Changes to the voice, rendering it squeaky, hoarse, or high-pitched.
- Flat feet.

QUESTIONS TO ASK YOUR DOCTOR

- What diagnostic criteria did you utilize to arrive at Werner syndrome?
- At what age should my child's heart be evaluated?
- Which family members should undergo genetic testing?
- What screenings for cancer should my child undergo?

In addition to the above signs and symptoms used for formal diagnostic purposes, other clinical observations have been reported, including loss of eyelashes and eyebrow hair, nail deformities, and the presence of thin limbs with a stocky trunk. A possible link to lung cancer has also been proposed.

In some cases, Werner syndrome can occur in a slower and milder partial form, with only some of the symptoms present.

Diagnosis

A definite diagnosis of Werner syndrome is established by the presence of all of the cardinal signs and symptoms listed above, plus at least two of the additional signs and symptoms.

A probable diagnosis is indicated by the presence of all of the first three cardinal signs, plus any two from the additional list.

A possible diagnosis is suggested by the presence of either cataracts or the skin manifestations, plus any four of the other signs or symptoms.

Werner syndrome may be ruled out if the signs and symptoms appear prior to adolescence. The exception to this rule is shortness of stature, because patterns of pre-adolescent growth are not sufficiently understood.

Diagnosis may involve x-rays to study hormone excretion, skin biopsies, and a blood-sugar test to determine whether diabetes mellitus is present. Werner syndrome can also be diagnosed by mutational analysis of the *WRN* gene.

Treatment and management

There is no known cure for Werner syndrome, so treatment is related to the specific symptoms present.

For example, cataracts can be corrected by surgery and skin ulcers can be treated with grafts.

Prognosis

Because it mimics the human aging process, Werner syndrome significantly reduces life expectancy in most patients. Average life expectancy for a Werner symptom patient is somewhere between 40 and 47 years. The most common causes of death are heart attacks, cerebrovascular accidents, and cancers.

Whole-exome and whole-genome sequencing

Definitions

Whole-exome sequencing (WES) is a genomic technique that has been developed since 2007 for identifying or determining the exact order of all the portions of the genes in an organism's genome that code for proteins. These gene portions are called exons, and the total of all the exons in a genome is called the exome. The human exome accounts for 180,000 exons, or 1% of all the DNA in an individual human's haploid genome—about 3.2 million base pairs. The word *exon* was formed from the words "EXpress" and "regiON", because the exon is the region of the gene expressed in the protein produced by the gene.

In most DNA sequences, the exons are separated by non-coding portions of the gene called introns. The word *intron* is derived from "INTragenic" and "regiON," because the introns are located inside the gene (intra-genic) between the exons. Prior to the process of amino acid transcription, the introns are spliced out of messenger RNA, leaving only the exons to transcribe the final gene product.

Whole-genome sequencing (WGS) is the sequencing of an organism's entire DNA at one time, including all of its chromosomal and mitochondrial DNA. WGS is also known as full genome sequencing, entire genome sequencing, or complete genome sequencing. Unlike WES, WGS can detect insertion or deletion mutations (indels), single nucleotide variants (SNVs), copy number changes, and large structural variations in the genome. It can also detect some variations in the exome that are missed by WES.

Until 2014, WGS was used primarily as a research tool, but it is increasingly used in clinical applications as of 2021. The first organism to have its entire genome sequenced was a bacterium, *Haemophilus influenzae*; its sequencing was completed in 1995 after automated methods sped up the process. In comparison to that of the human, the genome of *H. influenzae* is small—1,830,140 base pairs of DNA.

Description

Both WES and WGS utilize blood, skin, or saliva samples for DNA analysis related to human or animal disease or disease risk, although blood samples are preferred because they yield higher amounts of DNA and are less likely to be contaminated by bacteria. When bacterial DNA is to be analyzed, the organisms are taken from a laboratory culture plate and treated with chemicals

Scientists at the Food and Drug Administration's comparative genomics laboratory using the Pac-Bio whole-genome sequencing machine. (FDA/Michael J. Ermarth/Science Source)

to extract the DNA. Plant samples often require several steps of chemical treatment, followed by washing to free the DNA from the complex sugars and other materials found in plant matter.

Both WES and WGS are innovations in DNA sequencing that were developed shortly after 2005, when so-called next-generation sequencing—variously called high-throughput sequencing, massively parallel sequencing, and shotgun sequencing—technology was introduced. Next-generation sequencing was the first major breakthrough in sequencing DNA since the development of the Sanger method in 1977 by Frederick Sanger in the United Kingdom. The Sanger method was time-consuming, expensive, and limited to sections of DNA that were only about 1,000 base pairs (bp) in length. As a result, using the Sanger sequencing method—which was the state of the art in 1990—meant that the Human Genome Project required 13 years to complete its sequencing of a human genome, and the task had to be divided among several different research centers.

Next-generation sequencing is both faster and less expensive than the original Sanger method, as it can sequence many strands of DNA at the same time and also sequence longer sections of DNA than the Sanger method allowed. The phrase “shotgun sequencing” refers to the fact that next-generation sequencing methods break up, or shear, an organism’s entire genome into many small fragments, similar to the effect of a shotgun blast. The DNA segments are then copied millions of times by polymerase chain reaction (PCR). The population of DNA fragments ready for sequencing is called a DNA library. The library is loaded onto a sequencer, and the resulting millions of reads produced by the sequencer are read by a computer that identifies overlapping segments in the

fragments and uses them to place them in the correct order to reconstruct the full genome.

Whole-exome sequencing begins with shotgun shearing of a genome, followed by one of several so-called target-enrichment strategies to identify the exons in the genome and separate them from the noncoding regions. This step is called targeted capture. Several different biotech companies offer kits containing the reagents needed to capture the exons as well as the equipment to interpret the results. After the exons have been captured, the exome is sequenced. It can then be analyzed to identify disease-causing mutations that underlie rare Mendelian (monogenic) diseases.

High-throughput sequencing is used for whole-genome sequencing as well as whole-exome sequencing. WGS can be divided into large whole-genome sequencing (for genomes larger than 5 million bp) and small whole-genome sequencing (for genomes smaller than 5 million bp, which includes almost all bacteria and viruses). Since 2019, it has been possible to perform a WES run in as little as five minutes, and a WGS in about 55 minutes.

Purpose

Whole-exome sequencing

WES is often used to identify disease-causing gene mutations because it can identify variations in the protein-coding region of any gene rather than focusing on a few preselected genes. About 85% of all disease-causing mutations in humans can be found in the exome.

As of 2021, WES has a diagnostic utility of 20% to 30%, meaning that a diagnosis can be given to between a fifth and a third of individuals who had been previously undiagnosed but had traits or features that suggested a genetic disorder. The use of WES has increased since 2015, because improvements in high-throughput sequencing have lowered the cost, reduced laboratory turnaround time, and increased insurance coverage of WES testing. According to the Yale Center for Genome Analysis (YCGA), whole-exome sequencing can cost from \$176 to \$364, depending on whether the patient’s DNA is taken from a standard blood sample or from a cancerous tumor.

Whole-genome sequencing

WGS is used in research and in some clinical cases in which DNA variations outside the exome can lead to genetic mutations. As of 2021, WGS is most likely to be used when WES has not been helpful in identifying the location of a mutation or when time is critical. Some

KEY TERMS

Base pair (bp)—Any of the complementary nucleotide bases (adenine-thymine and cytosine-guanine in DNA; adenine-uracil and cytosine-guanine in RNA) held together by weak hydrogen bonds. Base pairs form links between the two strands of DNA.

Bioinformatics—An interdisciplinary scientific field that combines statistics, engineering, mathematics, and computer science to capture and understand biological data.

Cascade testing—A term that refers to performing genetic counseling and testing in blood relatives of a person identified as having a specific genetic mutation. It is most commonly recommended for the relatives of patients carrying a genetic mutation linked to cancer.

Ethics—The branch of philosophy that concerns questions of good and evil as well as moral duties and obligations in human society.

Exome—The part of a genome formed by all of its exons.

Exon—The DNA sequence of a gene that codes for a protein.

Genome—The complete genetic material of an organism.

Genome-wide association study (GWAS)—A method for identifying genes involved in human

disease by searching a number of human genomes for small variations that occur more commonly in people with a given disease than in those who do not have the disease.

Genomics—A subspecialty of genetics that focuses on the study of the genome.

Haploid—Referring to cells that have only one chromosome of each type, and therefore have only one complete set of genes. Gametes (sperm and eggs) normally have a haploid number of chromosomes.

Intron—Any of the portions of a gene that does not code for amino acids.

Mendelian disease—A disease caused by a single mutated gene; also called a single-gene disease. These diseases are named for Gregor Mendel (1822–1884), an Austrian monk who discovered the basic principles of inheritance of single-gene traits through experimentation with plants in his garden.

Monogenic disease—Another term for a single-gene disorder.

Next-generation sequencing—A general term for massively parallel sequencing of large portions of DNA base pairs, performed by first fragmenting the DNA, reading the individual fragments in parallel, and then reassembling the reads to obtain the sequence of the entire genome.

complex human disorders in which WGS has been used to arrive at a diagnosis include:

- intellectual disabilities and learning disorders
- developmental delays in walking and talking
- seizures and brain abnormalities
- hearing and vision disorders
- heart and lung disorders
- disorders of the digestive tract
- skeletal disorders, including short stature and abnormalities of the arms, legs, hands, and feet
- recurrent infections and immunodeficiencies
- severe unexplained illnesses

The advantages of WGS include the possibility of early intervention in the treatment of a diagnosed disorder, including a more personalized approach to the patient's therapy. In addition, WGS can provide the patient's family with information that they can use to decide whether other family members might benefit from genetic testing—an approach called cascade testing.

The cost of WGS has dropped considerably since the completion of the Human Genome Project in 2003. After 2006, a number of biotechnology companies began to compete to lower the price of a complete human genome to \$1,000, and “the \$1,000 genome” became a catchphrase among entrepreneurs interested in making WGS affordable to average persons. The National Human Genome Research Institute (NHGRI) began offering grant money to advance the development of a \$1,000 genome. Various companies, including Illumina and Veritas Genetics, claimed to have invented sequencing technologies that could produce a full human genome for \$1,000 by 2018. In 2019, the Yale Center for Genome Analysis charged \$949 for WGS. The price has dropped even further, with WGS being offered by one commercial company for as little as \$199 on the shopping holiday known as Black Friday in 2019.

Unlike WGS, however, insurance companies are less willing to share the cost of whole-genome sequencing. United Healthcare maintains in its most recent policy statement (issued on January 1, 2021) that “Whole

Nucleotide—A building block of a nucleic acid (DNA or RNA), consisting of a sugar molecule, a phosphate group, and one of the nitrogen-containing bases (adenine, cytosine, guanine, and thymine in DNA; adenine, cytosine, guanine, and uracil in RNA).

Personalized medicine—The tailoring of medical treatment to the individual patient based on his or her genetic profile. It is also called precision medicine.

Pharmacogenomics—The branch of medicine that studies the role of the human genome in response to medications.

Phenotype—The set of observable characteristics or traits of an organism. It includes physical form and structure, development, metabolic processes, movement, and behavior.

Polymerase chain reaction (PCR)—A method for replicating DNA fragments by using repeated cycles of heating and cooling to denature the DNA (separate it into two strands) and use an enzyme to make new copies of the original DNA.

PulseNet—A network of laboratories across the United States, overseen by the Centers for Disease Control and Prevention (CDC) to identify bacteria responsible for foodborne outbreaks by using whole-genome sequencing.

Sanger sequencing—The earliest method for sequencing DNA, devised by Frederick Sanger in the United Kingdom in 1977 and used as the primary method of sequencing until 2002. It is still used to validate the results of so-called next-generation sequencing. The Sanger method involves first separating the two strands of DNA and then adding chemically altered forms of the adenine, cytosine, guanine, and thymine bases. The altered bases stop the process of DNA replication as they are added to the strand of DNA, resulting in a series of short pieces of DNA. These short pieces are placed in order from shortest to longest to read the entire original sequence of DNA.

Secondary findings—Incidental or unanticipated findings, often of a previously unsuspected disease risk, resulting from the use of WES or WGS.

Throughput—In general, the rate at which data can be processed, or the work that a computer can do in a specific period of time. High-throughput sequencing refers to any of a set of technologies that can produce large numbers of DNA sequences concurrently.

Zoonosis (plural, zoonoses)—Any infectious disease of animals that can be transmitted to humans. A human disease that can be transmitted to animals is called a reverse zoonosis.

Genome Sequencing (WGS) is not medically necessary for evaluating any genetic disorder due to the availability of clinically equivalent diagnostic tests.” Other insurers will pay for WGS only for critically ill infants in a newborn intensive care unit (NICU).

Limitations

The primary limitation of WES is that it covers only a limited portion of the human genome; thus, DNA variations outside the exome that can influence genetic mutations will not be identified by WES. If a suspected disease-causing mutation is thought to be in the missing section of the exome, it must be identified by another method, most often whole-genome sequencing. This limitation of WES has led to a debate in the field of genomics regarding the future utility of exome sequencing. Some researchers are predicting that WES has a limited “shelf life,” and will be replaced entirely by WGS as the cost of whole-genome sequencing continues to drop. Others maintain that the shorter time frame required to perform WES (1/15 the time required to sequence an entire human

genome) and the smaller amount of data requiring storage (1/15 the volume required for WGS) will guarantee an ongoing place for whole-exome sequencing. The chief limitation of WGS is the much greater amount of computational power and data storage it requires.

Another limitation is that both WES and WGS sequencing identify a large number of single nucleotide variations (SNVs) of unknown significance as well as potentially disease-causing mutations. The number of such variations ranges from about 24,000 in African American samples to 20,000 in Caucasian Americans. Although there are several strategies for filtering out the non-problematic variations, there are usually several hundred SNVs remaining that require sorting and analysis by genetics professionals.

One related problem is the discovery of what are called secondary or incidental findings during whole-exome or whole-genome sequencing. A secondary finding is one that is not relevant to the condition for which the test was ordered but indicates the likelihood of future

disease in the person being tested; for example, the discovery of a mutation in one of the genes linked to breast cancer—an adult-onset disorder—in a small child being tested for mutations related to vision disorders. Secondary findings can cause considerable anxiety in patients. The risk of psychological distress is one that the genetic counselor should discuss with the patient before the sequencing is ordered.

Ethical concerns

The rapid pace of these new discoveries has led to a set of new ethical concerns for high-quality patient care as well as the most effective use of advanced technologies. In 2012, the American College of Medical Genetics and Genomics (ACMG) drew up a policy statement—which has not been updated as of 2021—regarding the clinical applications of whole-exome and whole-genome sequencing. Their first recommendation concerned the indications for WES and WGS in clinical diagnostic assessment. The ACMG recommended WES or WGS in the following situations:

- The patient's phenotype or family history suggests a genetic cause, but the patient's phenotype does not resemble that of a genetic disorder for which a clinical single-gene test currently exists.
- The patient has a genetic disorder with a high degree of genetic heterogeneity, making WES or WGS a more practical approach because both methods can analyze a number of different genes simultaneously.
- The patient is likely to have a genetic disorder, but the specific genetic tests presently available for that disorder have failed to yield a diagnosis.

The ACMG also recommended pre-test genetic counseling regarding the expected outcomes, the likelihood and reporting of secondary findings, and discussion of which results will or will not be disclosed to the patient. The patient is to be given the option of *not* receiving either diagnostically certain or secondary findings. In addition, the ACMG recommended obtaining informed consent from the patient for the use of findings of unknown significance that might be a subject for future research. Ongoing questions related to both WES and WGS include issues of permanent versus temporary data storage, patient confidentiality, obtaining informed consent from children and adolescent patients, and disclosure of WES and WGS findings to insurance companies.

In regard to using WES and WGS for health-screening purposes in asymptomatic patients, the ACMG stated that genomic sequencing should not be used for prenatal or newborn screening under present circumstances. Adult subjects should be given both pre-test and post-test counseling by a qualified medical geneticist or

QUESTIONS TO ASK YOUR DOCTOR

- Have any of your patients ever undergone WES or WGS?
- If so, were the results helpful in diagnosing or treating their health condition?
- Do you think that WES or WGS should be used routinely for health screenings in adults? Why or why not?
- What advances in personalized medicine do you expect to see in the next few years as a result of genomic sequencing?

genetic counselor. The counseling should cover both risks and benefits of genomic sequencing, plus the fact that the results will include “the virtual certainty of finding variants of uncertain significance.”

Epidemiology

Whole-genome sequencing has been used since 2013 by the CDC, and since 2018 by the FDA, in identifying foodborne bacteria and other biological contaminants. WGS has advantages over older methods of identifying disease-causing organisms in food, because it can distinguish genomic differences among bacteria or other contaminants, thus allowing scientists to trace the root source of a foodborne pathogen. The FDA has set up an open-access database called the GenomeTrackr, which archives WGS data for hundreds of thousands of bacterial samples. As of April 2021, there are over 600,000 WGS sequences in the GenomeTrackr, with an average of 12,000 new sequences added each month.

In 1996, the CDC established PulseNet, a network of 83 laboratories across the United States, in order to track outbreaks of foodborne illness and resolve them as quickly as possible. Until 2013, PulseNet used an older technology called pulsed-field gel electrophoresis (PFGE) to compare bacterial genomes. In 2013, WGS was introduced to solve outbreaks caused by *Listeria monocytogenes*, a virulent foodborne bacterium that can cause fatal illness in 20% to 30% of high-risk persons. The CDC found that the use of WGS resulted in solving more cases of *Listeria* outbreaks while simultaneously reducing the number of cases reported for each outbreak.

Another epidemiological application of WGS is its use in tracking infections passed between humans and other animals (zoonoses). A group of researchers in Texas concerned about the possibility of COVID-19

transmission between humans and household pets obtained samples of the virus from 76 cats and dogs sharing a household with at least one infected human, and analyzed the samples using WGS. Interestingly, the sequencing showed that humans were more likely to transmit the virus to their pets than the other way around—a form of transmission called reverse zoonosis.

Personalized medicine

Researchers are greatly interested in the use of WES and WGS to advance personalized medicine, also known as precision medicine. Personalized medicine is an approach to health care that uses genomic information about patients to make treatment decisions. These decisions could include the type of therapy offered to a patient, the choice of a specific medication, or careful monitoring of a patient known to be at increased risk of a specific disease or disorder. Personalized medicine allows for the use of information gained from WES and WGS to begin an intervention at an earlier stage in the patient's life. For example, a child who is revealed by WES to be at increased risk of developing type 2 diabetes in adult life can learn to eat a healthful diet, get adequate physical exercise, and make other lifestyle adjustments to lower the risk of adult-onset diabetes.

Pharmacogenomics, or the study of how a person's genome affects their response to medications, is a major part of personalized medicine. A growing number of cancer drugs, for example, are tailored to attack specific mutations, such as the three drugs currently used to treat melanomas caused by mutations in the *BRAF* gene. Other examples can be found in the field of psychiatry. Because a person's DNA affects how long an antidepressant or antipsychotic medication remains active in the body, genome sequencing can help identify the specific medication that is most likely to benefit the patient, as well as the most effective dosage of that medication.

Direct-to-consumer exome and genome sequencing

Various companies based in the United States and China began offering direct-to-consumer (DTC) exome sequencing tests as early as 2011. Whole-genome sequencing tests were offered a few years later. Although private individuals were able to purchase WGS for several years from such companies as Illumina, the whole-genome tests cost \$4,000 at that point in time and were marketed primarily to researchers. In 2011, a DTC genetic testing company called 23andMe offered a whole-exome sequencing test for \$999 but was forced to drop the health-related results formerly sent to customers

when the Food and Drug Administration (FDA) ordered the company to discontinue its personal genome service.

As of 2021, one company called Sequencing.com offers WGS to American consumers for \$399. According to the company, WGS testing in India is offered to consumers for prices ranging from \$338 to \$676. Another American company, Nebula, offers three tiers of WGS: “basic,” for \$149; “deep,” for \$299; and “ultra-deep” for \$999.

Genetics professionals are concerned about the trend toward DTC genomic sequencing, as it has already led to anxious consumers consulting genetic counselors on their own. As both whole-exome sequencing and whole-genome sequencing yield large amounts of complex data that are time-consuming to interpret, DTC marketing of sequencing tests is currently more likely to confuse and worry consumers than to help them. In addition, genetic counselors have noted the lack of adequate informed-consent provisions on many DTC genome-sequencing websites, along with incomplete or misleading information about the tests themselves.

Williams-Beuren syndrome see **Williams syndrome**

Williams syndrome

Definition

Williams syndrome is a genetic disorder caused by a deletion of a series of genes on chromosome 7q11. Individuals with the disorder have distinctive facial features, mild intellectual disability, heart and blood vessel problems, short stature, unique personality traits, and distinct learning abilities and deficits.

Description

Williams syndrome, also known as Williams Beuren syndrome, was first described in 1961 by Dr. J. C. P. Williams of New Zealand. At that time it was noted that individuals with the condition had an unusual constellation of physical and mental findings. The physical features include a characteristic facial appearance, heart and cardiovascular problems, high blood calcium levels, low birth weight, short stature, and other connective tissue abnormalities. The intellectual problems associated with Williams include a mild intellectual disability and a specific cognitive profile. That is, individuals with Williams syndrome often have the same pattern of learning abilities and disabilities, as well as many similar personality traits.

The findings in Williams syndrome are variable—that is, not all individuals with the disorder will have all of the described findings. In addition to being variable, the physical and mental findings associated with Williams syndrome are progressive—they change over time.

Genetic profile

Williams syndrome is a genetic disorder due to a deletion of chromosome material on the long arm of chromosome 7. A series of genes are located in this region. Individuals with Williams syndrome may have some or all of these genes deleted. Because of this, the condition is referred to as a contiguous gene deletion syndrome. Contiguous refers to the fact that these genes are arranged next to each other. The size of the deletion can be large or small, which may explain why some individuals with Williams syndrome are more severely affected than others. If you think of these genes as the letters of the alphabet, some individuals with the condition are missing A to M, some are missing G to Q, and others are missing A to R. While there are differences in the amount of genetic material that can be deleted, there is a region of overlap. Everyone in the example was missing G to M. It is thought that the missing genes in this region are important causes of the physical and mental findings of Williams syndrome.

Two genes in particular, *ELN* and *LIMK1*, have been shown to be important in causing some of the characteristic symptoms of Williams syndrome. The *ELN* gene codes for a protein called elastin. The job of elastin in the human body is to provide elasticity to the connective tissues such as those in the arteries, joints, and tendons. The exact role of the *LIMK1* gene is not known. The gene codes for a substance known as lim kinase 1 that is active in the brain. It is thought that the deletion of the *LIMK1* gene may be responsible for the visuospatial learning difficulties of individuals with Williams syndrome. Many other genes are known to be in the deleted region of chromosome 7q11 responsible for the disorder and much work is being done to determine the role of these genes in Williams syndrome.

Williams syndrome is an autosomal dominant disorder. Genes always come in pairs and in an autosomal dominant disorder, only one gene need be missing or altered for an individual to have the disorder. Although Williams syndrome is an autosomal disorder, most individuals with Williams syndrome are the only people in their family with this disorder. When this is the case, the chromosome deletion that causes Williams syndrome is called *de novo*. A *de novo* deletion is one that occurs for the first time in the affected individual. The cause of *de novo* chromosome deletions is unknown. Parents of an individual with Williams syndrome due to a *de novo* deletion are very unlikely to have a second child with the syndrome. However, once an individual has a chromosome deletion, there is a 50% chance that they will pass it on to their offspring. Thus individuals with Williams syndrome have a 50% chance of passing this deletion (and Williams syndrome) to their children.

Human chromosomes showing Williams syndrome. The chromosome marked 7 (lower right) shows four dots (genes). The chromosome marked del(7) [upper left] shows only one green area. (Addenbrookes Hospital/Science Source)

Demographics

Williams syndrome affects 1 in 10,000 people. Because Williams syndrome is an autosomal dominant disorder, it affects an equal number of males and females. It is thought that the condition occurs in people of all ethnic backgrounds equally.

Signs and symptoms

Williams syndrome is a multi-system disorder. In addition to distinct facial features, individuals can have cardiovascular, growth, joint, and other physical problems. They also share unique personality traits and have intellectual differences.

Infants with Williams syndrome are often born small for their family and 70% are diagnosed with failure to thrive during infancy. These growth problems continue throughout the life of a person with Williams syndrome and most individuals with the disorder have short stature (height below the third percentile). Infants with Williams syndrome can also be extremely irritable and have “colic-like” behavior. This behavior is thought to be due to excess calcium in the blood (hypercalcemia). Other problems that can occur in the first years include strabismus (crossed eyes), ear infections, chronic constipation, and eating problems.

Individuals with the condition can have distinct facial features sometimes described as “elfin” or “pixie-like.” While none of these individual facial features are abnormal, the combination of the different features is common for Williams syndrome. Individuals have a small upturned nose; a small chin; long upper lip with a

KEY TERMS

De novo deletion—A deletion that occurs for the first time in the affected individual. The cause of de novo deletions is not known.

Hypercalcemia—High levels of calcium in the blood.

Stellate—A star-like, lacy white pattern in the iris. Most often seen in light-eyed individuals.

wide mouth; small, widely spaced teeth, and puffiness around the eyes. As an individual gets older, these facial features become more pronounced.

People with Williams syndrome often have problems with narrowing of their heart and blood vessels. This is thought to be due to the deletion of the elastin gene and is called elastin arteriopathy. Any artery in the body can be affected but the most common narrowing is seen in the aorta of the heart. This condition is called supravalvar aortic stenosis (SVAS) and occurs in approximately 75% of individuals with the disorder. The degree of narrowing is variable. If left untreated, it can lead to high blood pressure, heart disease, and heart failure. The blood vessels that lead to the kidney and other organs can also be affected.

Deletions of the elastin gene are also thought to be responsible for the loose joints of some children with Williams syndrome. As individuals with the syndrome age, their heel cords and hamstrings tend to tighten, which can lead to a stiff awkward gait and curving of the spine.

Approximately 75% of individuals with the condition have mild intellectual disability. They also have a unique cognitive profile (unique learning abilities and disabilities). This cognitive profile is independent of their IQ. Individuals with Williams syndrome generally have excellent language and memorization skills. They can have extensive vocabularies and may develop a thorough knowledge of a topic that they are interested in. Many individuals are also gifted musicians. Individuals with Williams syndrome have trouble with concepts that rely on visuospatial ability. Because of this, many people with the disorder have trouble with math, writing, and drawing.

People with Williams syndrome also often share personality characteristics. They are noted to be very talkative and friendly—sometimes inappropriately—and they can be hyperactive. Another shared personality trait is a generalized anxiety.

Diagnosis

The diagnosis of Williams syndrome is usually made by a physician familiar with the disorder and based upon a physical examination of the individual and a review of his or her medical history. It is often made in infants after a heart problem (usually SVAS) is diagnosed. In children without significant heart problems, the diagnosis may be made after enrollment in school when they are noted to be “slow learners.”

While a diagnosis can be made based upon physical examination and medical history, the diagnosis can now be confirmed by a DNA test.

Williams syndrome is caused by a deletion of genetic material from the long arm of chromosome 7. A specific technique called fluorescent in situ hybridization testing, or FISH testing, can determine whether there is genetic material missing. A FISH test will be positive (detect a deletion) in more than 99% of individuals with the disorder. A negative FISH test for Williams syndrome means that no genetic material is missing from the critical region on chromosome 7q11.

Prenatal testing (testing during pregnancy) for Williams syndrome is possible using the FISH test on DNA sample obtained by chorionic villus sampling (CVS) or by amniocentesis. Chorionic villus sampling is a prenatal test that is usually done between 10 to 12 weeks of pregnancy and involves removing a small amount of tissue from the placenta. Amniocentesis is a prenatal test that is usually performed at 16–18 weeks of pregnancy and involves removing a small amount of the amniotic fluid that surrounds the fetus. DNA is obtained from these samples and tested to see if the deletion responsible for the condition is present. While prenatal testing is possible, it is not routinely performed. Typically, the test is only done if there is a family history of Williams syndrome.

Treatment and management

Because Williams syndrome is a multi-system disorder, the expertise of a number of specialists is required for management of this disorder.

The height and growth of individuals with Williams syndrome should be monitored using special growth curves developed specifically for individuals with the disorder. Individuals who fall off these growth curves should be worked up for possible eating or thyroid disorders.

A cardiologist should evaluate individuals with Williams syndrome yearly. This examination should include measurement of blood pressure in all four limbs and an echocardiogram of the heart. An echocardiogram is a special form of ultrasound that looks at the structure of the heart. Doppler flow studies, which look at how the blood

QUESTIONS TO ASK YOUR DOCTOR

- How does the Williams syndrome growth chart differ from other growth charts, and where does my child fall on it?
- Can you recommend a nutritionist?
- Is my child's blood pressure within the normal range?
- What are the risks and benefits of medications used to manage behavior?

flows into and out of the heart, should also be done. Individuals with supravulvar stenosis may require surgery to fix this condition. The high blood pressure caused by this condition may be treated with medication. Examinations should take place yearly as some of these conditions are progressive and may worsen over time.

Individuals with Williams syndrome should also have a complete neurological examination. In addition, the blood calcium levels of individuals with the disorder should be monitored every two years. High levels of calcium can cause irritability, vomiting, constipation, and muscle cramps. An individual found to have a high level of calcium should consult a nutritionist to make sure that their intake of calcium is not higher than 100% of the recommended daily allowance (RDA). Because vitamin D can increase calcium levels, individuals with Williams syndrome and high calcium should not take multivitamins containing vitamin D. If calcium levels remain high after limiting vitamin D and decreasing dietary intake of calcium, an individual with hypercalcemia should see a nephrologist for further management and to monitor kidney function.

Strabismus (crossed eyes) can be treated by patching or by surgery. Ear infections can be treated with antibiotics and surgical placement of ear tubes.

The developmental differences of individuals with Williams syndrome should be treated with early intervention and special education classes. Specific learning strategies that capitalize on the strengths of individuals with the condition should be used. Physical, occupational, and speech therapy should be provided. Behavioral counseling and medication may help with behavioral problems such as hyperactivity and anxiety.

Prognosis

The prognosis for individuals with Williams syndrome is highly dependent on the medical complications of a particular individual. Individuals with the disorder

who have no heart complications, or very minor ones, have a good prognosis. Good medical care and treatment of potential problems allows most individuals with Williams syndrome to lead a long life. The prognosis for individuals with more serious medical complications such as severe heart disease or hypertension is more guarded. Since the medical conditions associated with the condition are progressive rather than static, it is very important that individuals with Williams syndrome have yearly medical examinations with a health care provider familiar with the disorder.

The range of abilities among individuals with Williams syndrome is very wide, and the ultimate functioning of an individual is dependent on his or her abilities. While individuals do well in structured environments such as school, their unique abilities and disabilities do not permit them to do as well in unstructured surroundings. Some individuals live independently but most live with their parents or in a supervised setting. Many individuals can gain employment in supervised settings and do well at tasks that do not require mathematics or visuospatial abilities. It is important to encourage individuals with Williams syndrome toward independence but to recognize that their friendly and outgoing personalities may lead them into abusive situations.

Wilson disease

Definition

Wilson disease is a rare, inherited disorder that causes excess copper to accumulate in the body. Steadily increasing amounts of copper circulating in the blood are deposited primarily in the brain, liver, kidneys, and the cornea of the eyes.

Description

Under normal conditions, copper that finds its way into the body through the diet is processed within the liver. This processed form of copper is then passed into the gallbladder, along with the other components of bile (a fluid produced by the liver that enters the small intestine in order to help in digestive processes). When the gallbladder empties its contents into the first part of the small intestine (duodenum), the copper in the bile enters and passes through the intestine with the waste products

of digestion. In healthy individuals, copper is then passed out of the body in stool.

In Wilson disease, copper does not pass from the liver into the bile, but rather begins to accumulate within the liver. As copper levels rise in the liver, the damaged organ begins to allow copper to flow into the bloodstream, where it circulates. Copper is then deposited throughout the body, building up primarily in the kidneys, the brain and nervous system, and the eyes. Wilson disease, then, is a disorder of copper poisoning occurring from birth.

Genetic profile

Wilson disease is inherited in an autosomal recessive manner. "Autosomal recessive" refers to the pattern of inheritance in which each parent carries a gene mutation for the disease on one of his or her chromosome pairs. When each parent passes on the chromosome with the gene mutation for Wilson disease, the child will be affected with the disease. Both males and females can be affected by Wilson disease. If an individual is a carrier of the Wilson disease gene, he or she does not have any symptoms of the disorder. In order to be affected, an individual must inherit two copies of the gene, one from each parent. Many cases of Wilson disease may not be inherited but occur as a spontaneous mutation in the gene.

Wilson Disease: pedigree analysis chart (Gale)

Illustration of the signs and symptoms of Wilson disease.
(Designua/Shutterstock)

The gene for Wilson disease, *ATP7B*, is located on chromosome 13 and is thought to be involved in transporting copper. More than 500 different mutations of this gene have been identified, making diagnosis by genetic testing difficult.

Demographics

Wilson disease affects approximately 1 in 30,000 to 1 in 100,000 individuals and can affect people from many different populations. In some isolated regions of Sardinia, the prevalence is reported to be 1 in 10,000 individuals. Approximately 1 in 90 individuals are carriers of the gene for Wilson disease.

Signs and symptoms

Symptoms typically present between the ages of 3 and 60, with age 17 considered to be the average age of diagnosis. About half of all patients experience their first symptoms in the liver. The illness causes swelling and tenderness of the liver, sometimes with fever, mimicking more common disorders such as viral hepatitis and infectious mononucleosis. Abnormal levels of circulating liver enzymes reveal that the liver is being seriously damaged. This form of damage is referred to as “fatty degeneration.” Without medical intervention, the liver damage will progress to actual cirrhosis. An often-fatal manifestation of liver disease is called fulminant hepatitis. This extremely severe inflammation of the liver (hepatitis)

results in jaundice, fluid leaking into the abdomen, low protein circulating in the blood, abnormalities of the blood clotting system, swelling of the brain, and anemia due to the abnormal destruction of red blood cells.

Neurological symptoms are the first to occur in half of all patients due to copper accumulation in the brain and nervous system. The average age of onset for neurological symptoms is 21 years. These symptoms include tremors of the hands, uncontrollable movements of the limbs, stiffness, drooling, difficulty swallowing, difficulty talking, and headache. There is no change in a patient’s intelligence.

About one-third of all patients with Wilson disease have a variety of psychiatric symptoms as the first signs of the disease. These symptoms include inability to cope, depression, irritability, increased anger, and inappropriate behavior. Patients often have trouble completing tasks at work or in school.

Other symptoms that can affect patients with Wilson disease, and that may occur before or after a diagnosis has been made, include joint disorders, symptoms of arthritis, and skeletal problems such as osteoporosis. Patients have occasionally been affected with kidney stones and abnormal handling of glucose in their body, and women have menstrual cycle irregularities including temporary stopping of their regular cycle.

Diagnosis

The diagnosis of Wilson disease can be performed relatively easily through several different tests that can be performed on patients who have or have not already shown symptoms of the disease. Although Wilson disease is so rare that diagnosis is often delayed, it is extremely important to make a diagnosis as soon as possible since liver damage can occur before there are any signs of the disease.

An easy way to diagnose Wilson disease is to measure the amount of a glycoprotein found in the blood called ceruloplasmin. Low levels of ceruloplasmin can diagnose the disease in about 80% of affected patients. This procedure is not as effective for women taking birth control pills, pregnant women, or infants less than six months of age.

A second test involving an eye examination to detect a characteristic ring of copper deposited in a membrane of the cornea (referred to as Kayser-Fleischer rings) is very easy to perform and is very useful in diagnosing patients who have already exhibited symptoms. This test is not as effective in persons without symptoms and cannot be used by itself to make a diagnosis because some patients with liver disease, but not Wilson disease, will test positive.

KEY TERMS

Anemia—A blood condition in which the level of hemoglobin or the number of red blood cells falls below normal values. Common symptoms include paleness, fatigue, and shortness of breath.

Bile—A substance produced by the liver and concentrated and stored in the gallbladder. Bile contains a number of different substances, including bile salts, cholesterol, and bilirubin.

Biopsy—The surgical removal and microscopic examination of living tissue for diagnostic purposes.

Cell—The smallest living units of the body that group together to form tissues and help the body perform specific functions.

Ceruloplasmin—A protein circulating in the bloodstream that binds with copper and transports it.

Chromosome—A microscopic thread-like structure found within each cell of the body that consists of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Changes in either the total number of chromosomes or their shape and size (structure) may lead to physical or mental abnormalities.

Cirrhosis—A chronic degenerative disease of the liver in which normal cells are replaced by fibrous tissue. Cirrhosis is a major risk factor for the later development of liver cancer.

Deoxyribonucleic acid (DNA)—The genetic material in cells that holds the inherited instructions for growth, development, and cellular functioning.

Gallbladder—A small, pear-shaped organ in the upper right hand corner of the abdomen. It is connected by a series of ducts (tube-like channels) to the liver, pancreas, and duodenum (first part of the small intestine). The gallbladder receives bile from the liver and concentrates and stores it. After a meal, bile is squeezed out of the gallbladder into the intestine, where it aids in digestion of food.

Gene—A building block of inheritance that contains the instructions for the production of a particular protein and is made up of a molecular sequence found on a section of DNA. Each gene is found on a precise location on a chromosome.

Glucose—One of the two simple sugars, together with galactose, that makes up the protein lactose, found in milk. Glucose is the form of sugar that is usable by the body to generate energy.

Hepatitis—A viral disease characterized by inflammation of the liver cells (hepatocytes). People infected with hepatitis B or hepatitis C virus are at an increased risk for developing liver cancer.

Jaundice—Yellowing of the skin or eyes due to excess of bilirubin in the blood.

Toxic—Poisonous.

A third test for diagnosing Wilson disease involves measuring the amount of copper in the liver. This can be accomplished by sampling a portion of the liver in a procedure called a biopsy. This is one of the most effective ways to diagnose Wilson disease; however, the procedure itself is more difficult to perform than the others.

Other tests are also useful; for example, measuring the amount of copper passed into the urine daily (high in Wilson disease). Another lab test measures the ability of a patient's ceruloplasmin to bind with a form of copper (decreased in Wilson disease). Some patients can be diagnosed through a DNA test to determine whether or not they carry two genes for Wilson disease. This test does not always prove to be useful in certain patients and is used mostly to test the brothers and sisters of affected patients.

Treatment and management

Treatment involves life-long administration of either D-penicillamine or trientine hydrochloride. Both of these

drugs remove copper deposits throughout the body by binding to the copper, which is removed from the body in urine. Zinc acetate and a low copper diet are other ways to treat Wilson disease.

Penicillamine has a number of serious side effects:

- joint pain
- neurological problems
- systemic lupus erythematosus
- decreased production of all blood elements
- interference with clotting
- allergic reactions

Careful monitoring is necessary. When patients have side effects from penicillamine, the dose can sometimes be lowered to an effective level that causes fewer difficulties. Alternatively, steroid medications may be required to reduce certain sensitivity reactions. Trientine has fewer potential side effects, but it must still be carefully monitored.

QUESTIONS TO ASK YOUR DOCTOR

- Can you recommend a low copper diet?
- What are the side effects of penicillamine?
- What are the pros and cons of zinc treatment versus medication for removing copper?
- How accurate is the genetic testing for Wilson disease?
- Are there any new therapies available to treat Wilson disease?

Treatment with zinc is also an effective way to remove excess copper from the body. Zinc is a metal that works to block copper absorption and bind copper in the intestinal cells until it is all released into the stool approximately one week later. The benefit of treatment with zinc is that there are no toxic side effects; however, zinc is a slower acting agent than the other drugs. It takes four to eight months for the zinc to be effective in reducing the overall amount of copper in the body.

In special situations in which individuals with Wilson disease do not respond to these treatments, a liver transplant is considered.

Finally, patients with Wilson disease are encouraged to follow a diet low in copper, with an average copper intake of 1.0 mg/day. Foods to avoid due to their high levels of copper include liver and shellfish. Patients are also instructed to monitor their drinking water for excess levels of copper and drink distilled water instead.

Prognosis

Without treatment, Wilson disease is always fatal. With treatment, symptoms may continue to worsen for the first six to eight weeks. After this time, definite improvement should start to be seen. However, it may take several years (two to five) of treatment to reach maximal benefit to the brain and liver. Even then, many patients are not returned to their original level of functioning. Patients with Wilson disease need to maintain some sort of anti-copper treatment for the rest of their lives in order to prevent copper levels from rising in the body. Interruptions in treatment can result in a relapse of the disease that is not reversible and can ultimately lead to death.

Wiskott-Aldrich syndrome

Definition

Wiskott-Aldrich syndrome (WAS) is a rare inherited disorder marked by a low level of blood platelets, eczema, immunodeficiency, and a high risk of leukemia or lymph node tumors.

Description

WAS was named for the two physicians who first reported the disorder. In 1937, Dr. Alfred Wiskott, a physician working in Munich, described two affected boys of German ancestry who had repeated infections, a skin

Wiskott-Aldrich Syndrome

X-Linked Recessive

Wiskott-Aldrich syndrome: pedigree analysis chart (Gale)

rash, and poor blood-clotting ability. Nearly 20 years later, Dr. Robert Aldrich reported similar symptoms in members of an American family of Dutch ancestry.

The syndrome is caused by a defect (mutation) in a specific gene called the *WAS* gene that normally codes for the Wiskott-Aldrich syndrome protein (WASp). This vital protein is a component of cells that are important in the body's defense against infection (lymphocytes). The same protein also functions in the cells that help prevent bleeding (platelets). A less severe form of the disease, X-linked thrombocytopenia, affects mainly the platelets.

Genetic profile

WAS is inherited as an X-linked genetic disorder and will therefore only affect males. The gene responsible for WAS is located on the short arm of the X chromosome. Since males have only one X chromosome, they only have one copy of the gene. If that copy carries the abnormal gene, they will have WAS. In contrast, females have two X chromosomes. They will have a normal copy of the gene on one chromosome even if an abnormal gene is on the other because the abnormal gene is very rare. The normal copy on one X chromosome is usually

sufficient to prevent females from having WAS. However, women who have one abnormal copy of the *WAS* gene are designated as carriers. While they will not have WAS, they have a 50% risk of passing the gene to each of their sons, who will then have WAS. Carrier females also have a 50% risk of passing the defective copy of the gene to their daughters, who then become carriers.

Researchers identified the gene for WAS in 1994 and pinpointed its location on the short arm of the X chromosome (Xp11.22-p11.23). More than 100 different mutations have been found in the gene among WAS patients. The fact that there are many mutations may explain some of the variability of symptoms among boys with WAS. However, even within the same family, affected individuals with the identical *WAS* gene mutation may have different degrees of severity of the disease. The mild form, X-linked thrombocytopenia, is also caused by mutations in this same gene. The *WAS* gene codes for the WASp protein, a protein necessary for blood cell development. A mutation in the *WAS* gene causes a disruption in the actin cytoskeleton, which is important for the structure of the cell itself. An alteration in the structure of the cell leads to an alteration in the function of the cell. White blood cells that have an alteration in the WASp protein,

KEY TERMS

Amniocentesis—A procedure performed at 16–18 weeks of pregnancy in which a needle is inserted through a woman’s abdomen into her uterus to draw out a small sample of the amniotic fluid from around the baby. Either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Anemia—A blood condition in which the level of hemoglobin or the number of red blood cells falls below normal values. Common symptoms include paleness, fatigue, and shortness of breath.

Chorionic villus sampling (CVS)—A procedure used for prenatal diagnosis at 10–12 weeks gestation. Under ultrasound guidance a needle is inserted through either the mother’s vagina or abdominal wall and a sample of cells is collected from around the fetus. These cells are then tested for chromosome abnormalities or other genetic diseases.

Eczema—Inflammation of the skin with redness and other variable signs such as crusts, watery discharge, and itching.

Gene—A building block of inheritance that contains the instructions for the production of a particular protein and is made up of a molecular sequence found on a section of DNA. Each gene is found at a precise location on a chromosome.

Immune system—The complex group of organs and cells that defends the body against infection and disease.

Mutation—An inherited or de novo change in the DNA sequence of the genome.

Platelets—Small disc-shaped structures that circulate in the blood stream and participate in blood clotting.

Prenatal diagnosis—The determination of whether a fetus possesses a disease or disorder while it is still in the womb.

Syndrome—A group of signs and symptoms that collectively characterize a disease or disorder.

Thrombocytopenia—A persistent decrease in the number of blood platelets; usually associated with hemorrhaging.

X-linked—A genetic trait that is carried on the X chromosome.

therefore, are unable to properly respond to pathogens, leading to a decrease in the overall function of the immune system. A lack of WASp protein in other blood cells such as platelets will result in an altered shape of the cell and cause early cell death, hence the low levels of platelets seen in WAS.

Demographics

WAS occurs worldwide and affects 1 in every 10 million male children. It is even less prevalent in women due to its X-linked inheritance pattern.

Signs and symptoms

Increased susceptibility to infections, eczema, and excessive bleeding are the hallmarks of WAS, although the symptoms can vary significantly from one patient to another. The immune system of a patient with WAS produces too few B and T cells. B cells are the cells in the body that make antibodies. There are many types of T cells. Both B and T cells are needed to defend the body against infection. Because both types of cells are affected, WAS patients are subject to repeated infections from bacteria, fungi, and viruses. Ear infections, meningitis, and pneumonia are common in boys with WAS.

WAS patients also have thrombocytopenia, a decreased number of platelets. Platelets are the specialized blood cells that help to form blood clots and prevent uncontrolled bleeding. The platelets may also be smaller than normal. Some of the earliest symptoms of the syndrome are hemorrhage from circumcision, bloody diarrhea, and a tendency to bruise very easily.

Anemia and an enlarged spleen (splenomegaly) are seen in some patients. About 10% of patients develop malignancies, usually leukemia or tumors in the lymph nodes (non-Hodgkin lymphoma).

Diagnosis

The diagnosis of WAS is usually suspected in male infants who have excessive bleeding, eczema, frequent bacterial or viral infections, bloody diarrhea, petechiae, or purpura. Special blood tests can then be ordered to confirm WAS. These blood tests are imperative because WAS may be confused with other bleeding disorders, and correct treatment given early is important for the prognosis of the individual. The blood of patients with WAS will show a low platelet count (less than 70,000/mL), a decreased amount of IgM and IgG with normal to high levels of IgA and IgE, and a decreased antibody response, particularly when assessed after routine vaccinations such as DPT (diphtheria, pertussis, and tetanus). It is also possible to confirm the diagnosis by obtaining a small sample of the patient’s blood and analyzing the

QUESTIONS TO ASK YOUR DOCTOR

- Which family members should undergo genetic testing for Wiskott Aldrich syndrome?
- Do you recommend removal of the spleen?
- What family members could be potential bone marrow donors?
- What are the risks and benefits of immune globulin?
- What are the treatment options for Wiskott Aldrich syndrome?
- What is the prognosis in this case?

DNA for a mutation in the WAS gene. Knowledge of the exact mutation combined with information about how much WASp protein the defective gene can produce may help predict how severe a form of the disease an individual will have.

Carrier testing

If the specific WAS gene mutation is identified in an affected child, that child's mother can then be tested to confirm that she carries the gene. Other members of the mother's family may also want to consider testing to find out if they carry the same gene mutation. The first step in studying other family members is for a geneticist or genetic counselor to obtain a detailed family history and construct a pedigree (family tree) to determine which family members should be offered testing.

Prenatal diagnosis

In families in which there has been one child born with WAS, prenatal testing should be offered in subsequent pregnancies. There is a 50% chance with each subsequent pregnancy that the mother, who is a carrier, will transmit the abnormal copy of the gene to her baby. The key is to first identify the particular WAS gene mutation in the child with WAS. Then, early in a pregnancy, cells can be obtained from the developing fetus by chorionic villus sampling or amniocentesis and checked for the same mutation. Women who carry the abnormal WAS gene and are considering prenatal diagnosis should discuss the risks and benefits of this type of testing with a geneticist or genetic counselor.

Treatment and management

Standard treatments for individuals with WAS include antibiotics for infections and platelet transfusions

to limit bleeding. Immune globulin replacement therapy is given every 4–6 weeks starting at age six months to strengthen the individual's immune system. Bloodwork should be evaluated routinely as well for the management of WAS. Eczema can be treated with corticosteroid creams applied directly to the skin. The spleen is sometimes removed to reduce the risk of bleeding. In individuals with WAS, however, removal of the spleen also increases the risk of infection unless antibiotics are given to prevent infections. About 50% of individuals with WAS are helped by treatment with transfer factor, which is a substance derived from the T cells of a healthy person. Transfer factor is given to improve both blood clotting and immune functions. Bone marrow transplantation has been successful in a number of cases. It has been most successful in boys under five years of age when the donor is a sibling whose tissue type closely matches that of the individual with WAS. As of 2015, the most effective treatment for WAS was the use of hematopoietic cell transplantation (HCT). Hematopoietic stem cell gene therapy using peripheral blood, umbilical cord blood, and/or bone marrow is also critical for the treatment of WAS in very young infants. Prenatal diagnosis is necessary to utilize this treatment method.

Prognosis

The prognosis for males diagnosed with WAS syndrome is poor. The average individual lives about four years. Forty percent of those who survive into adolescence often develop other autoimmune diseases typically causing liver and/or kidney failure, and/or cancer. Death usually occurs from severe bleeding or overwhelming infection in the first few years of life.

Wolf-Hirschhorn syndrome

Definition

Wolf-Hirschhorn syndrome (WHS) refers to a condition that is caused by a deletion of the short arm of chromosome 4. This missing genetic material results in severe developmental retardation and a characteristic facial appearance, and it may include a variety of other birth defects.

Description

This syndrome was reported in 1965 in published reports by Wolf and Hirschhorn, who associated specific physical characteristics with a deletion of part of the short arm of chromosome 4. The short arm of a chromosome is called the “p” arm. Thus, this syndrome is also known as 4p- syndrome or deletion 4p- syndrome, and occasionally as Wolf syndrome.

A normal human karyotype consists of 23 pairs of chromosomes. Each pair is numbered 1 through 22, and the 23rd pair is made by the sex chromosomes. On each chromosome are hundreds of genes that determine how human bodies look and function. WHS is a contiguous gene syndrome that is defined as a gene syndrome in which deletions or duplications in the same region of the chromosome occur, affecting the genes on those chromosomes. Each time a deletion or duplication of those genes occurs, they cause specific characteristics that define a particular syndrome. This is in contrast to having just one particular gene cause a syndrome. Some patients who have WHS may have a small deletion on 4p, while others may be missing up to half of 4p. For this reason, some individuals have a less severe case of WHS than others do. The band 4p16.3 needs to be deleted in order for an individual to have full expression of WHS.

WHS frequently presents prenatally with slow growth (intrauterine growth retardation). Some infants with WHS can be stillborn or die shortly after birth, and

as many as one-third of reported patients with WHS have died in the first year of life. Individuals with WHS have been described as having a characteristic facial appearance likened to a “Greek Helmet facies.” This can be described as having small head size (microcephaly), eyes spaced widely apart (ocular hypertelorism), downturned mouth, short upper lip, short groove between the upper lip and nose (philtrum), or bilateral cleft lip and small chin (micrognathia).

Children with WHS have severe developmental delays. Other significant problems can include heart defects, cleft lip and/or palate, hearing impairment, and eye problems. Approximately 90% of children who have WHS have seizures. These seizures begin between 5 and 23 months of age; however, approximately 50% of the individuals stop having seizures between age 3 and 11. Sleeping problems are also common in children who have WHS. Although it seems that most of the literature focuses on children who have WHS, there are adults who have the disease.

Genetic profile

With routine chromosome analysis, it is possible to identify missing parts of the short arm of chromosome 4. The size of the missing material may vary from patient to patient. At times, the deletion is so small that it cannot be detected by routine chromosome analysis. If a patient is suspected to have WHS and an obvious deletion is not detected by routine chromosome analysis, more detailed studies are warranted and may identify the missing genetic material. WHS may also present as mosaicism. Mosaicism for 4p- syndrome means that the individual has some cells that have normal number 4 chromosomes and other cells that are missing some of the genetic material from chromosome 4.

Approximately 85%–90% of cases of WHS occur as the result of a new deletion in the affected individual. This is also known as a *de novo* deletion and simply means that the affected individual’s parents did not have any chromosome arrangement that led to the deletion. In this case, the chance for recurrence in future pregnancies of a couple who has an affected child is not increased. In the remaining 10%–15% of cases, one of the parents of the affected individual carries a balanced translocation. A balanced translocation is a rearrangement in the individual’s chromosomes that causes that individual no problems since he or she has all the necessary genetic material needed. However, when the individual produces eggs or sperm, the eggs or sperm may end up with an unbalanced arrangement and could lead to the conception of a child who has missing or extra genetic material. This could lead to miscarriage or to the birth of a child with conditions like WHS.

When a parent is identified as being a carrier of a balanced translocation, with each pregnancy he or she has an increased chance of having a child with an unbalanced chromosome arrangement. This probability is determined by the individual's specific translocation, how it was identified, and which parent is the carrier of the translocation. Genetic counseling should be offered to any family in which a child is diagnosed with WHS. Other family members should also be offered counseling and chromosome analysis to determine if they are carriers of a balanced translocation.

Demographics

The incidence of this condition is rare and estimated to be approximately 1 in 50,000 births. As with many genetic conditions, WHS may be misdiagnosed or may not be diagnosed in all individuals who are affected, especially if the condition results in pregnancy loss or loss in the early newborn period. It has been estimated that approximately 35% of individuals who have WHS die within the first two years of life. Also, with the advent of prenatal diagnosis, some fetuses with ultrasound abnormalities may be detected early, and the parents may elect to terminate the pregnancy. Approximately two-thirds of reported cases have been females.

Signs and symptoms

It is important to remember that each individual who may have a particular genetic syndrome is a unique individual. Therefore, all individuals with WHS do not have all of the same signs and symptoms. An accurate diagnosis helps to determine the needs of each person, based on the histories available from other individuals affected with the same condition.

Signs and symptoms that can be associated with WHS include the following:

- slow growth before birth
- slow growth after birth (postnatal growth deficiency)
- small head size (microcephaly)
- weak cry in infancy
- poor muscle tone (hypotonia)
- seizures
- severe developmental delays
- severe delay of motor skills
- crossed eyes (strabismus)
- widely spaced eyes (hypertelorism)
- droopy eyelids (ptosis)
- skin folds in the corner of the eyes (epicanthal folds)
- cleft lip and/or palate

KEY TERMS

Amniocentesis—A procedure performed at 16–18 weeks of pregnancy in which a needle is inserted through a woman's abdomen and into her uterus to draw out a small sample of the amniotic fluid from around the fetus. Either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Chorionic villus sampling (CVS)—A procedure used for prenatal diagnosis at 10–12 weeks gestation. Under ultrasound guidance a needle is inserted through either the woman's vagina or abdominal wall and a sample of cells is collected from around the fetus. These cells are then tested for chromosome abnormalities or other genetic diseases.

Chromosome translocation—The exchange of genetic material between chromosomes, which can lead to extra or missing genetic material.

Corpus callosum—A thick bundle of nerve fibers deep in the center of the forebrain that provides communications between the right and left cerebral hemispheres.

In vitro fertilization—A process by which a woman has her eggs surgically removed and fertilized in the laboratory. The developing embryos can then be transferred to her uterus to hopefully achieve a pregnancy.

- short upper lip and philtrum
- small chin (micrognathia)
- asymmetry of the skull (cranial asymmetry)
- skin tag or pit in front of the ear (preauricular tag or pit)
- downturned mouth
- prominent triangular area of the forehead (glabella)
- scalp defects on the center of the back of the head
- underdeveloped fingerprints (dermal ridges)
- a single crease across the palm of the hands (simian crease)
- misaligned bones in the front part of the foot/clubfoot (talipes equinovarus)
- turned up fingernails
- urinary opening on the underside of the penis (hypospadias)
- undescended testicles (cryptorchidism)
- dimple at the base of the spine
- heart defects

- curvature of the spine (scoliosis)
- underdeveloped bones of the hands and pelvis

Diagnosis

When WHS is suspected, chromosome analysis should be performed and the laboratory should be informed as to what syndrome is suspected. This ensures that the laboratory carefully looks at chromosome 4, and if the deletion is not visible, then fluorescent in situ hybridization (FISH) can be done specifically for the critical 4p16.3 region of chromosome 4. FISH analysis is a procedure that is used in the laboratory to identify pieces of genetic material that are too small to see by looking at the chromosome under a microscope. Instead, DNA that is specific to a particular area of a chromosome is fluorescently labeled so that it is visible under the microscope. This labeled DNA is then added to the sample and allowed to attach itself to the particular piece of DNA in question. This enables the laboratory technician to then look under the microscope for the fluorescent spot on the chromosome and identify extra or missing pieces of DNA that are too small to see by just looking at the chromosome alone. With this procedure, those individuals who have deletions so small that they cannot be detected by routine chromosome analysis may be able to have the deletion detected by FISH.

Interestingly, a syndrome called Pitt-Rogers-Danks syndrome (PRDS) has been reported to have similar characteristics to WHS. Several individuals who were initially diagnosed with PRDS subsequently had FISH analysis that detected a deletion of 4p, and thus the individuals were reclassified as having WHS. Some feel that PRDS is actually WHS without obvious deletions of 4p.

When a couple has had a child diagnosed with the inherited form of WHS, a member of that couple carries a balanced translocation, and genetic counseling should be offered to discuss reproductive options. One option is choosing sperm or egg donation so that the parent who has the translocation does not pass unbalanced genetic material on to his or her future child. Another option is preimplantation genetic diagnosis. Preimplantation genetic diagnosis is a very complex process that involves in vitro fertilization and diagnosing the embryos before they are placed into the mother's uterus. Thus, only unaffected embryos are transferred to the uterus. Lastly, the options of CVS and amniocentesis for prenatal diagnosis should be discussed. All of these options have allowed couples with balanced translocations to evaluate their choice of having more children.

If ultrasound examination reveals findings consistent with the possibility of WHS in a family with no history of WHS, genetic counseling and prenatal diagnosis should

QUESTIONS TO ASK YOUR DOCTOR

- At what point should my child be evaluated for a heart disorder?
- When should my child's hearing be evaluated?
- When should my child see an ophthalmologist?
- What developmental programs or resources do you recommend?
- What is my status as a carrier for WHS if other family members have the disease?

be offered. These ultrasound findings may include heart defects, microcephaly, agenesis of the corpus collosum (missing a specific part of the brain), micrognathia, cleft lip and palate, a hole in the diaphragm (diaphragmatic hernia), hypospadias, and clubbed feet. While all these symptoms are consistent with WHS, they can also be evidence of other genetic syndromes.

Treatment and management

There is no treatment for the underlying condition of WHS. Treatment and management for patients who have WHS are specific to each individual. For example, some individuals who have WHS may have heart defects or a cleft lip and/or palate that may require surgery, while others may not. Therefore, there is no specific treatment for individuals who have WHS; rather, the treatment and management are geared toward that particular individual's needs and are likely to include several medical specialists. Information about patients who have WHS has been compiled and provides a comprehensive look into the natural history of this condition. It also allows management guidelines to be recommended. The collection of this information has shown that many of these individuals may achieve more development than was previously believed possible.

The management recommendations that have been made include:

- Feeding problems should be addressed and may require intervention such as placement of a gastrostomy tube.
- Characterization of seizures is important, and treatment with antiepileptic medications such as valproic acid should be investigated and may help control the seizure activity in many individuals.
- Skeletal abnormalities such as clubfoot should be addressed, and treatment should be considered. It should not be assumed that clubfoot does not need to be

addressed because the child will never walk. Children with WHS have learned to walk unassisted.

- Approximately 30% of individuals may have congenital heart defects, so the heart should be examined. Usually the heart lesions are not severe and may be repaired easily or may not even require surgery.
- Hearing loss may occur, and because some children are able to learn to talk in short sentences, they should be screened for hearing problems.
- Eye abnormalities may be present; therefore, an ophthalmology exam should be performed to rule out any eye problems, even if no obvious signs are present.
- With regard to the development of patients with WHS, it is suggested that individuals participate in personal development programs to assist with social skills and occupational therapy for motor skills.

Prognosis

Infants who have WHS may be stillborn or die in the newborn period, and prognosis during the newborn period depends upon what birth defects are present. It has been estimated that approximately 35% of individuals who have WHS die within the first two years of life, but many individuals who have WHS survive to adulthood. Universally, children with WHS have severe or profound developmental retardation; however, there are many affected individuals who are able to walk and some who are able to talk in short sentences. It is evident that many patients seem to proceed farther than was previously thought possible. The actual lifespan for individuals who have WHS is unknown, although there are several individuals who have WHS who are in their 20s, 30s, and 40s.

and Emily R. Larson, PhD

Wolman disease

Definition

Wolman disease is a rare inherited defect in the body's metabolism of fats (lipids) caused by a loss of function of the lysosomal acid lipase enzyme.

Description

Wolman disease, also known as lysosomal acid lipase disease, is a lethal genetic disorder caused by the lack of the enzyme lysosomal acid lipase. Lysosomal acid lipase is a cellular enzyme widespread throughout the body and is important in the breakdown of certain lipids called triglycerides and cholesteryl esters. Individuals without an active enzyme accumulate abnormally large amounts of these lipids in their cells. This build-up interferes with the normal cellular metabolic functions and leads to severe neurological and physical symptoms and early death. A milder disease, cholesteryl ester storage disease (CESD), is caused by mutations in the same gene but affected individuals may not show symptoms until adulthood.

Genetic profile

Inheritance pattern

Wolman disease is an autosomal recessive disorder affecting both males and females. In individuals with this disorder, both copies of the *LIPA* gene that codes for lysosomal acid lipase are abnormal. Both parents of an affected child have one abnormal copy of *LIPA* but usually do not show symptoms because they also have one normal copy. The normal copy provides approximately 50% of the usual enzyme activity, a level adequate for the body's needs. Individuals with one abnormal copy of the

KEY TERMS

Adrenal gland—A triangle-shaped endocrine gland, located above each kidney, that synthesizes aldosterone, cortisol, and testosterone from cholesterol. The adrenal glands are responsible for salt and water levels in the body, as well as for protein, fat, and carbohydrate metabolism.

Amniocentesis—A procedure performed at 16–18 weeks of pregnancy in which a needle is inserted through a woman's abdomen into her uterus to draw out a small sample of the amniotic fluid from around the baby. Either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Autosomal recessive—A pattern of genetic inheritance where two abnormal genes are needed to display the trait or disease.

Carrier—A person who possesses a gene for an abnormal trait without showing signs of the disorder. The person may pass the abnormal gene on to offspring.

Chorionic villus sampling—A procedure used for prenatal diagnosis at 10–12 weeks gestation. Under ultrasound guidance a needle is inserted either through the mother's vagina or abdominal wall and

a sample of cells is collected from around the early embryo. These cells are then tested for chromosome abnormalities or other genetic diseases.

Enzyme—A protein that catalyzes a biochemical reaction or change without changing its own structure or function.

Gene—A building block of inheritance, which contains the instructions for the production of a particular protein, and is made up of a molecular sequence found on a section of DNA. Each gene is found on a precise location on a chromosome.

Heterozygote—Having two different versions of the same gene.

Lysosomal—Pertaining to the lysosomes, special parts (organelles) of cells that contain a number of enzymes important in the breakdown of large molecules such as proteins and fats.

Lysosomal acid lipase—An enzyme that catalyzes the hydrolytic breakdown of lipids in the lysosome. This enzyme is coded by the LIPA gene.

Mutation—A permanent change in the genetic material that may alter a trait or characteristic of an individual, or manifest as disease, and can be transmitted to offspring.

LIPA gene and 50% enzyme activity are said to be carriers or heterozygotes. Because both parents of a child with Wolman disease are carriers, they have a 25% risk in each subsequent pregnancy of having another child who is affected with the same disorder.

Gene location

The gene for acid lipase is located on the long arm of chromosome 10 at position 10q23.2-q23.3. A number of different types of mutations in this gene all result in a lack of enzyme function and have been identified in patients diagnosed with Wolman disease. These include deletions of small portions of the gene, as well as changes in the sequence of specific nucleotides. The different mutations may explain the variations in symptoms observed in Wolman patients. However, symptoms may vary even among siblings who have inherited the same mutations from their parents, suggesting there may be other genetic or environmental factors that affect the presentation of the disease. Milder forms, such as the related disorder CESD, appear to be associated with gene mutations that result in only partial loss of enzyme function.

Demographics

In the general population Wolman disease is exceedingly rare, with approximately 50 or fewer well-described cases to date. CESD is thought to be more common. Individuals with Wolman disease have been reported in various parts of the world including Western Europe, North America, Iraq, Iran, Israel, China, and Japan.

Signs and symptoms

Symptoms of Wolman disease appear in the first few weeks of life. Forceful vomiting and distention of the abdomen are usually the first symptoms presented. Other general symptoms in the early stages of this disease are watery diarrhea or fat in the stool, fever, and a yellow tint to the skin (jaundice). Medical examination can reveal massive enlargement of the liver and spleen (hepatosplenomegaly) due to a build-up of fats that cannot be broken down. Other common findings are severe anemia, calcium deposits in the adrenal glands, and a general decline in mental development.

QUESTIONS TO ASK YOUR DOCTOR

- Do you recommend a low-fat diet?
- What are the risks and expected benefits of cholesterol controlling medication?
- Have you heard reports of enzyme replacement for Wolman disease?
- Do you think liver transplant is a possibility?
- If I am a carrier of Wolman disease, what are the chances my children will have it?

Diagnosis

Diagnosis can be difficult because there are no general laboratory tests that point specifically to Wolman disease. Infants with hepatosplenomegaly and evidence of malnutrition should have a careful neurological examination and x-rays of the abdomen to check for calcium deposits in the adrenal glands. If Wolman disease is suspected on the basis of these tests, acid lipase activity can be measured in the laboratory using white blood cells or skin cells. An absence of acid lipase activity confirms the diagnosis.

Carrier testing

Individuals suspected of being a carrier of Wolman disease can have their diagnosis confirmed by measuring acid lipase activity in their white blood cells. Carriers will typically demonstrate 50% of normal enzyme activity.

Mutation detection

Specific DNA tests that check for changes in the normal sequence of nucleotides in the *LIPA* gene can usually detect the particular gene mutation in an affected individual or carrier. This type of test is only available in a few, very specialized DNA laboratories.

Prenatal diagnosis

Couples who have had one child with Wolman disease may be offered prenatal testing in future pregnancies. Prenatal testing is accomplished by measuring acid lipase activity either in cells from a chorionic villus sampling (CVS) at 10–12 weeks of pregnancy, or in amniotic fluid cells obtained by amniocentesis between 16–18 weeks of pregnancy. Alternatively, if specific gene

mutations have been identified in parents because they have already had an affected child, fetal DNA from chorionic villi cells or amniotic fluid cells can be studied to look for these same mutations in the fetus. Carrier couples that are considering prenatal diagnosis should discuss the risks and benefits of this type of testing with a geneticist or genetic counselor.

Treatment and management

There is no specific treatment for Wolman disease. There have been attempts to treat the milder CESD with low-fat diets and cholesterol-lowering drugs, and there has been at least one report of a liver transplant in a patient with CESD. Replacement of the missing enzyme has not been reported.

Prognosis

Infants diagnosed with Wolman disease usually die by six months of age. As of 2009, the oldest recorded ages of surviving Wolman patients were 4 and 11 years. Both patients had received stem cell treatments.

X-linked intellectual disability

Definition

X-linked intellectual disability (XLID), formerly known as X-linked mental retardation, broadly refers to a group of inherited disorders characterized by varying degrees of intellectual disability caused by mutations in various genes present on the X chromosome. Intellectual disability is defined as the failure to develop cognitive abilities and achieve a level of intelligence and adaptive behavior that is appropriate for a particular age group. XLID is mostly seen in boys, usually manifests before the age of 18, and is characterized by an overall intelligence quotient (IQ) of less than 70, along with functional deficits in adaptive behavior like daily living, social, and communication skills.

Description

The X chromosome was so named initially to mean unknown, as the functions of the genes carried on it were not clear. The United States Census of 1890 was the first to collect data that showed that more boys than girls were mentally disabled, and later it was suspected that this was due to the difference in the sex chromosomes present in males and females. It was only in 1970 that the most common cause of XLID, fragile X syndrome, was described in detail; its mutated gene (*FMR1*) was not identified until 1991. Mutations in the *MECP2* gene are the second most common cause of XLID, and result in Rett's syndrome. This gene was identified in 1999. Since 2004, about 200 XLID disease types have been described. With the help of the Human Genome Project, of the 150–200 candidate genes on the X chromosome, mutations in about 100 have been identified as being responsible for different XLID diseases.

XLID is broadly divided into syndromic and non-syndromic disorders. Syndromic XLID (S-XLID) refers to conditions in which intellectual disability is accompanied by characteristic and easily recognizable physical

and/or neurological features. In non-syndromic XLID (NS-XLID), intellectual disability is the only key feature without any other distinctive physical or neurological features. Two-thirds of XLID cases are thought to be non-syndromic. In both syndromic and non-syndromic XLID, affected persons are mostly boys who have developmental delay or intellectual disability of variable severity and who usually have another affected male maternal relative such as a maternal uncle. With rapid advances in genetics afforded by the Human Genome Project, it is now possible to detect most of the mutations known to cause intellectual disability even before the child is born, leading to effective counseling and prevention strategies.

X-linked intellectual disability was formerly called X-linked mental retardation; however, at the request of patient advocacy groups, in January 2013 the United States federal government proposed a terminology change in all official documents to replace “mental retardation” with the term “intellectual disability.” This change was enacted, and all documents from the U.S. government no longer use the term “mental retardation.” Most patients and parents welcomed this change and consider the use of “mental retardation” to be pejorative.

Genetic profile

The different diagnoses of X-linked intellectual disability are among the most common forms of inherited intellectual disability, with fragile X being the most common form of inherited intellectual disability after Down syndrome. There are more than 100 different specific mutations of genes on the X chromosome that cause intellectual disability.

As of August 2015, mutations on the following genes located on the X-chromosome were known to cause XLID: *ABCD1*, *ACSL4*, *ACTB*, *ACTG1*, *AFF2*, *AMMECR1*, *ARX*, *ARFGEF2*, *ARHGEF6*, *ATP6AP2*, *ATP7A*, *ATRX*, *BCAP31*, *BCOR*, *BRWD3*, *CACNA1F*, *CASK*, *CCDC22*, *CDKL5*, *CLCN5*, *CLIC2*, *CUL4B*, *DCX*, *DLAT*, *DLG3*, *FBXO25* (translocation X;8),

FGD1, FLNA, FMRI, FTSJ1, GDII, GPC3, GRIA3, HCFC1, HDAC8, HPRT1, HSD17B10, HUWE1, IDS, IGBP1, IKBKG, IL1RAPL2, IQSEC2, KCNE5, KDM5C, KDM6A, L1CAM, LAMP2, MAOA, MECP2, MED12, MID1, MID2, NHS, NIPBL, NLGN3, NLGN4X, NPDP, OCRL, OFD1, OPHN1, OTC, PAFAH1B1, PAK3, PDHA1, PDHB, PDHX, PDP1, PGK1, PHF6, PHF8, PLP1, PORCN, PQBP1, PRPS1, RAB39B, RAB40AL, RELN, RPL10, RPS6KA3, SHROOM4, SLC6A8, SLC9A6, SLC16A2, SMC1A, SMC3, SMS, SOX3, SPECC1L, SRPX2, SYP, TSPAN7, TUBA1A, UBE2A, UPF3B, USP9X, YWHAE, ZC4H2, ZDHHC9, ZDHHC15, ZMYM3, ZNF711, and ZNF81.

The complete sequence of the X chromosome was identified in 2005, and it confirmed that an unusually large number of its genes carry information for proteins important for brain functions. Most of the mutated genes in XLID are “intelligence” genes that influence development, cell migration, formation and maintenance of neural networks, and cell-to-cell communication in the brain. The majority of the genes identified are linked to syndromic XLID, while the majority of individuals with XLID do not have a known syndrome. Different mutations in the same gene can give rise to either S-XLID or NS-XLID.

Females have two X chromosomes, and males have one X and one Y chromosome (which determines the male sex). The X chromosome in the male is always derived from the mother. A female uses only one of her two X chromosomes in each cell and randomly inactivates the other X chromosome. Thus, if only one of her X chromosomes has a defective gene, only some of her cells will suffer. The severity of XLID in the female will consequently depend on the percentage of cells in which the mutated gene is expressed. On the other hand, men have only one X chromosome, so any defective genes from that chromosome are invariably expressed.

Demographics

About 2%–3% of the population has intellectual disability due to genetic and non-genetic factors such as birth injuries, infections, and developmental anomalies. XLID is thought to account for approximately 20% of genetic causes of intellectual disability and accounts for the 20%–30% excess of intellectual disability observed in males in comparison to females. Although accurate numbers are difficult to estimate, the prevalence of XLID may be approximately 1 in 600 males and 1 in 400 female carriers.

Signs and symptoms

There are many different conditions and syndromes associated with XLID. These can either be malformation syndromes, in which affected patients have intellectual

disability and multiple birth defects; neuromuscular syndromes, in which patients have intellectual disability and abnormalities in various nerves and muscles; metabolic syndromes have a defect in a specific biochemical pathway; or dominant syndromes in which the disorder is inherited in an X-linked dominant fashion with most affected males dying before birth.

The most common known cause of inherited intellectual disability is fragile X syndrome, which accounts for 20% of XLID. It was first described in the late 1970s; the gene was discovered in 1991. People from all ethnic and social backgrounds can be affected. It results from a mutation in the fragile X intellectual disability (*FMRI*) gene found on the X chromosome. This gene contains information needed for making the FMR protein, which is thought to regulate communication between various cells by eliminating unwanted communication neural pathways.

The *FMRI* gene contains two distinct regions, one of which is called the promoter region. This region is composed of repeating units or building blocks called nucleotides arranged in a specific sequence. A normal person has 30 such units and can make normal amounts of the FMR protein. When a person has between 55 and 200 units, the gene becomes partially inactivated. They can still make some amount of FMR protein and are said to have a pre-mutation. The pre-mutation occurs in 1 in 250–300 females and 1 in 1,000 males. The amount of FMR protein in the body determines the severity of effects due to fragile X. Therefore, patients with a pre-mutation may have few, if any, symptoms and may not even know that they are carrying an abnormal gene. A pre-mutation can be transmitted silently over generations, but with each generation, the number of units increases and there is a higher chance of manifesting the condition (anticipation).

When a person has more than 200 units, the gene itself becomes completely inactivated, making it impossible to produce any FMR protein. The full mutation occurs in 1 in 3,600 males and 1 in 4,000–6,000 females. As females have two X chromosomes in each cell, even if one X has the full mutation, the other X carries the normal *FMRI* gene, making it possible to produce at least some FMR protein. Therefore, females are less often and less seriously affected than males. Females who do not express the disease, but carry the abnormal gene are called carriers.

If a father carries the *FMRI* mutation, he will transmit the mutation to all his daughters but cannot transmit it to his sons, as males receive only the Y chromosome. On the other hand, if a mother carries the mutation on one of her X chromosomes, each of her children (boys

or girls) will have a 50% chance of inheriting the *FMR1* mutation, depending on which X chromosome they receive.

There is a considerable variability in disease severity of fragile X syndrome in males, with many of the physical symptoms becoming more apparent only after puberty. Prior to puberty, the most common findings include speech delay, developmental delay, and intellectual disability. The most noticeable and consistent effect is on intelligence. More than 80% of affected males have an IQ of less than 70, whereas the effect on IQ in an affected female is variable. It is uncommon for persons with fragile X to have severe intellectual disability, and most have IQ in the range of 40–85. Females may show normal cognitive development with only mild learning disabilities and a normal IQ. People with fragile X have good memory skills for pictures and visual patterns, but have poor verbal knowledge. They also have poor abstract thinking, organizational skills, and problem-solving capabilities. Despite such limitations, many of them can be trained to acquire jobs and skills to take care of themselves.

Children with fragile X tend to develop certain physical characteristics by the time of puberty. They have a long face or jaw, large protruding ears, and do not grow as tall as other members in the family. Males with fragile X have large testicles, but this does not affect sexual development. They also have problems with connective tissues. They may be flat footed, have loose hyper-extensible joints, and “floppy” heart valves. Later in life, they can manifest hand tremors and difficulty walking. Women with fragile X undergo menopause early due to premature cessation of ovarian function affecting their reproductive capabilities. About 25% of patients have seizures.

Most people with fragile X syndrome, especially boys, have anxiety in social situations and become nervous and uncomfortable. They also tend to be easily upset and overwhelmed by sensory stimulation due to sights and sounds and deviance from normal routine. This may emerge as aggression in adolescent boys. Females tend to have less anxiety and are not usually aggressive. Boys have language problems, including speaking, writing, and acquiring social communication skills. Common behavior disturbances include attention deficit disorder, repetitive hand flapping, autistic behaviors, and gaze aversion. Twenty percent of these individuals meet full criteria for autism.

Rett’s syndrome (RS) is the second leading cause of XLID and the leading cause of intellectual disability in girls. It was first described in 1966; the gene was identified in 1999. RS is caused by mutation in the *MECP2* gene that causes abnormal truncation of the gene. The *MECP2* gene contains information for production of

methyl cytosine binding protein 2, which normally helps to turn off other genes appropriately at various points along the process of brain development. If this does not occur, the overactive genes interfere with normal brain maturation and lead to abnormal “wiring” and overload of the brain’s electrical system. Other types of mutation in the same *MECP2* gene can result in mild intellectual disability, tremor, psychosis, or learning disability, both in boys and girls, without producing classic RS.

RS occurs almost exclusively in females and has a prevalence of 1 in 10,000–20,000. In males, the mutation is lethal, and most are severely affected or die before or soon after birth. There is also a phenomenon of preferential inactivation of the normal X chromosome leading to the disease expression even in the female. The affected girl develops normally during the first five months of life. During this period, the child exhibits autistic behaviors. She can be calm and quiet, without making good eye contact, and without showing much interest in toys. After this, head growth slows down and the child loses whatever purposeful hand movements that had already developed. Around three years of age, the girl develops repetitive hand washing or hand wringing gestures, loses ability to speak, has trouble sleeping, becomes irritable, and develops an unsteady gait. Varying degrees of intellectual disability are present. These children also have seizures.

West syndrome, also known as the infantile spasm intellectual disability syndrome, is caused by mutations in the *ARX* (aristaless-related homeobox) gene. This is the third most common genetic mutation leading to XLID. It can occur in both boys and girls and is characterized by developmental delay, intellectual disability, and a specific type of seizures called salaam fits or infantile spasms. During the seizures, the children either have a flexion spasm where the body is bent over in a self-hugging position or an extension spasm where the neck and body are arched backwards.

Mutations in the *ARX* gene can also result in various developmental defects like lissencephaly (smooth brain), absence of the corpus callosum, microcephaly, and urinary and genital abnormalities, without causing the classic West syndrome.

Non-syndromic X-linked intellectual disability (NS-XLID) is represented by a heterogeneous group of disorders in which the only recognizable abnormality is intellectual disability without other accompanying physical manifestations.

Diagnosis

The diagnosis of XLID should be considered in all children with autistic behaviors, intellectual disability,

KEY TERMS

Amniotic fluid—The liquid that surrounds and cushions the developing fetus inside the mother's womb.

Anticipation—The apparent tendency of certain diseases to appear at earlier age and with increasing severity in successive generations.

Anomaly—A malformation or abnormality in any part of the body.

Attention deficit disorder—Neurological condition that is often evident from childhood, characterized by restlessness, disorganization, hyperactivity, distractibility, and mood swings.

Autism—A chronic developmental disorder usually diagnosed between 18 and 30 months of age; symptoms include problems with social interaction and communication, as well as repetitive interests and activities.

Carrier—An individual who possesses an unexpressed abnormal gene of a recessive genetic disorder.

Chorionic villus—Cells that are present in the placenta that can be used for genetic analysis.

Chromosome—A thread-like structure that is present in the nucleus of all cells and contains DNA, which carries genetic information.

Cognitive—Brain functions involved in the ability to think, learn, and remember.

Connective tissue—Tissue that is the supporting framework of the body and its internal organs; made up of collagen, elastic fibers, and fat.

Corpus callosum—Tightly bundled nerve fibers that connect the right and left hemispheres of the brain.

Deoxyribonucleic acid (DNA)—A chemical found primarily in the nucleus of cells, which carries the instructions for making all the structures and materials the body needs to function.

Gene—The basic unit of heredity; a sequence of DNA nucleotides on a chromosome.

Human Genome Project—An international effort begun in 1990 to locate and identify the 100,000 genes on the 46 human chromosomes.

Lissencephaly—A developmental disorder where the brain is smooth without the normal surface convolutions.

Menopause—The transition in a woman's life whereby menstrual periods stop.

Microcephaly—A condition, present at birth, in which the head is much smaller than normal for an infant of that age and gender.

Mutation—A spontaneous change in the sequence of nucleotides in a chromosome or gene.

Neural—Pertaining to a nerve or the nervous system.

Nucleotide—A small molecule composed of three parts: a nitrogen base (a purine or pyrimidine), a sugar (ribose or deoxyribose), and phosphate; they serve as the building blocks of nucleic acids (DNA and RNA).

Placenta—A bag-like organ that partially surrounds the fetus during pregnancy; it delivers oxygen and nutrients to, and takes waste away from, the fetus during pregnancy, and is attached to the fetus by the umbilical cord.

Promoter—The region of a gene that initiates transcription of the genetic information.

Psychosis—A severe mental disorder characterized by loss of contact with reality, causing deterioration of normal social functioning.

Seizures—An abnormal electrical discharge from the brain that usually results in convulsion of the body.

Syndrome—The group or recognizable pattern of symptoms or abnormalities that indicate a particular trait or disease.

developmental delay, or unexplained speech delay; 80%–90% of patients with fragile X syndrome are not yet correctly diagnosed. Because the symptoms of fragile X can be quite subtle, especially in young children, and because it is so frequent in the general population, many medical specialists recommend routine testing for fragile X syndrome. This is, however, not a regular screening test for all children. Testing for *FMR1* mutation is possible in people of any age and even before birth.

A variety of diagnostic tests based on DNA, chromosomal, or protein analysis is available. Chromosomal tests look for the fragile, or broken, portion of the X chromosome under a microscope, but are generally not very sensitive. Protein tests measure the amount of FMR protein produced by the cells and can determine the severity of the disorder. A DNA-based test to diagnose fragile X was developed in 1992 and is based on detecting an increased number of repeating units. This test is quite

accurate, and it can detect both carriers and fully affected individuals. Samples from blood, hair root, or a scraping from inside the cheek can be used to carry out the test. In a pregnant woman, amniotic fluid or cells from the placenta, called chorionic villi, are used to detect the mutation. Similarly, genetic testing can be done in specialized laboratories for the other common gene mutations associated with XLID, such as Rett's syndrome.

With the advent of next-generation sequencing (NGS), a genetic screening that provides the ability to sequence an individual's entire genome, it is now possible to identify the exact X chromosome mutation involved in most cases of XLID.

Treatment and management

Currently, there is no cure for any of the conditions associated with XLID. Best results are obtained when medications are combined with educational, social, and occupational therapy. Early intervention when the child's brain is still developing is advocated in order to maximize its long-term potential. A team comprising of a neurologist, genetic specialist, psychologist, behavioral specialist, physical, occupational, and speech therapists should work with the family and caregivers to ensure that the child receives appropriate therapy based on individual needs. This team can also assess the patient's level of independence and ensure appropriate transition from adolescent to young adult.

The U.S. Food and Drug Administration Agency (FDA) has not approved any specific medication for treatment of fragile X or its symptoms. But several medications have been tried on an empiric basis to ameliorate specific symptoms and problems associated with this disorder. Seizures and mood instability can be treated with drugs used primarily in epilepsy, such as carbamazepine, valproate, gabapentin, and topiramate.

The Individuals with Disabilities Act of 1997 ensures free education for children with intellectual disability and special cognitive needs until high school or until they reach 21 years. This law also ensures that children are taught in a non-restrictive environment tailored to their special needs. Speech therapists can help in language acquisition and devise innovative ways for nonverbal communication. Occupational therapists can assist the child with adaptive equipment to help overcome physical disabilities. Physical therapists help in designing programs and activities to promote posture, gait, and balance. Behavioral therapists can work with the family and the child in identifying strategies and coping skills to deal with social situations and avoiding aggression.

The Fragile X Research Foundation (FRAXA) funds several endeavors to help find a cure for this disease.

Ongoing research is focused on repairing the defective gene, replacing the defective gene, supplying the deficient protein, or substituting the deficient protein with another protein.

Prognosis

The prognosis for children with XLID varies depending on whether they have a syndrome with other features that may limit life expectancy. Children with fragile X syndrome, like most children with XLID, have a fairly normal life expectancy. With early diagnosis and treatment, they can grow into independent individuals. Similarly, children with Rett's syndrome usually survive to adulthood and middle age.

X-linked severe combined immunodeficiency

Definition

X-linked severe combined immunodeficiency (X-SCID) is a genetic disorder of the immune system that primarily affects males. It is the most common of the various forms of severe combined immunodeficiency (SCID). Symptoms can be present at birth. Males with the disorder are prone to recurrent and persistent infections due to their compromised immune systems.

Description

X-SCID is a hereditary disease, meaning it is passed from parent to child. It is considered a rare disorder by the National Institutes of Health (NIH). It is often called “Bubble Boy” disease based on a Texas boy who spent his entire life inside a germ-free environment, or “bubble.” The boy, David Vetter, died in 1984 at age 12 after a bone marrow transplant failed. Boys with X-linked SCID are susceptible to opportunistic infections that can occur over and over and are resistant to standard antibiotic treatment. The infections are called opportunistic because they do not normally cause sickness in healthy people. In people with the disorder, the body’s immune system, which normally fights off infections, is severely compromised or does not work at all, making any infection serious and potentially life-threatening. Without treatment, infants with the disorder usually die within the first couple of years after birth. The primary treatment is a bone marrow transplant.

The disorder is genetic, meaning it is inherited from a parent. Yet more than half of boys with the disease have no family history of early deaths in male relatives on their mother’s side, according to the NIH.

Genetic profile

X-SCID is an X-linked condition, meaning the gene for the disorder is found on the X chromosome. This is also known as a sex-linked condition affecting primarily males. Males and not females are affected because males

KEY TERMS

Bone marrow—The soft and spongy center of the bones where blood cells are made.

Chromosomes—Structures inside cells that carry an individual’s genetic information.

DNA—Deoxyribonucleic acid, the basic building blocks of all life on Earth. DNA stores genetic information that is passed from parents to their offspring.

Flow cytometry—A method of analyzing cells in which cell properties are detected as they flow in a narrow stream through a measuring device.

Hereditary—The passing of traits from parents to their offspring.

Immune system—The complex group of organs and cells that defends the body against infection and disease.

Lymphocytes—White blood cells that fight infection and disease.

Mutated gene—A change of DNA sequence that causes a change of the function of the gene and a subsequent disease.

Opportunistic infections—Infections that would not usually cause illness in people with a healthy immune system.

Preimplantation genetic diagnosis—Genetic testing performed on a developing embryo conceived through in vitro fertilization (IVF). The unaffected (non-disease carrying) embryos are transferred back into the womb for implantation.

Prenatal testing—Testing for a disease such as a genetic condition in an unborn baby.

are born with an X chromosome passed from their mother and a Y chromosome passed from their father. Women are born with two X chromosomes, one from their mother and one from their father. When women have a mutation for a genetic condition on one X chromosome, the other X chromosome will compensate for the mutated gene. Males who inherit the X chromosome with a gene mutation for SCID from their mother will not have a complementary copy of the gene since they have only one X chromosome.

The gene that is mutated in X-SCID is known as the *IL2RG* gene. A woman who carries an *IL2RG* mutation has a 50% chance of transmitting the gene to each child she bears. Her sons who inherit the mutation will get the

disorder, but any daughters will become carriers; they will not get the disorder. In contrast, men who have the mutated gene will pass it on to their daughters but not their sons. Prenatal testing is available for pregnant women who are known carriers of the gene mutation.

Demographics

The prevalence of X-SCID is unknown but likely affects at least 1 in 50,000 to 1 in 100,000 newborns in the United States and worldwide. However, since there are no routine screening programs to determine the true incidence, some experts say the estimate may be too small. All ethnic groups are affected equally by the disorder.

Signs and symptoms

X-SCID is caused by mutations in the *IL2RG* gene, which provides information for making a protein that is required for the immune system to function normally. It is the immune system's job to fight infections in the body using a variety of cells, including lymphocytes (a type of white blood cells in the immune system.) Mutations in the *IL2RG* gene prevent lymphocyte cells from developing normally. With damaged lymphocytes, the immune system cannot fight off infections.

Symptoms can start at birth, but more commonly problems are first noticed between three and six months of age. By one year of age, virtually all males with the disorder express symptoms. They include persistent and frequent infections caused by bacteria, viruses, and fungi that a healthy immune system would fight off. Common infections in infants include influenza, pneumonia, and infections of the ear and urinary tract. Other symptoms include rashes, diarrhea, cough, congestion, fever, other autoimmune conditions, failure to thrive, and short stature. Infants are often born without tonsils and lymph nodes.

Diagnosis

Diagnosis is usually made by measuring the amount of lymphocytes in the body, lymphocyte cell surface staining and counting by flow cytometry, and lymphocyte functional tests. When the number of absolute lymphocytes is low, the number of T cells is extremely low, B cells do not work, and the number of natural killer cells is low or zero. T cells are a type of white blood cell involved in rejecting foreign tissue, regulating immunity, and controlling the production of antibodies to fight infection. B cells are a class of lymphocytes, released from the bone marrow, that produce antibodies. Natural killer cells are specialized immune system cells that kill target cells infected with viruses or host cells that have become cancerous.

QUESTIONS TO ASK YOUR DOCTOR

- Do you know of any recent research or medical breakthroughs concerning my child's condition?
- Would alternative or complementary treatments be useful in treating any of my child's symptoms?
- Are there any current or planned clinical trials or studies of this disorder that my child might be eligible to participate in?
- What are the chances of having another affected child?

Examination

Diagnosis of the disorder is only through specific tests, not physical examination.

Genetic tests

X-SCID can also be diagnosed with genetic testing. Molecular genetic testing allows extra time to search for bone marrow transplant donors. It can also allow treatment to begin shortly after birth rather than waiting a few months for symptoms to appear. More than 99% of affected males will carry a mutation on the *IL2RG* gene found on the X chromosome. Many states now include X-SCID on a newborn screening panel. Prenatal testing and pre-implantation genetic diagnosis are also possible when the *IL2RG* gene mutation has been identified in a family.

Treatment and management

Bone marrow transplant is the primary treatment for X-SCID, although gene therapies have been successfully used since 1990. Since then, several European studies have shown that gene therapy is a successful treatment, although in a few cases, the side effects included leukemia, a potentially fatal cancer of the blood.

The primary treatment is usually a bone marrow transplant from a parent or other relative.

Interim treatment while the immune system is being restored includes treating infections with antibiotics and immunoglobulin infusion. Immunoglobulin is a class of proteins that act as antibodies in the immune system. Long-term treatment includes continued infusions of immunoglobulin and gene therapy using stem cells. Gene therapy is primarily used in children who are either unable to have a bone marrow transplant or in whom bone marrow transplantation has failed.

Prognosis

Infants and children with X-SCID need quick action to restore a healthy or healthier immune system to survive. Untreated infants usually do not live beyond a year.

The survival rate is not clear, and the oldest survivors have lived into their 30s, according to the National Center for Biotechnology Information. This may be changing as more research is done and new treatment possibilities are studied. Further advancement in gene therapy, especially stem cell research, may increase life expectancy. Children who have had successful bone marrow transplants should be evaluated by a physician every 6 to 12 months.

X-linked sideroblastic anemia

Definition

X-linked sideroblastic anemia is a hereditary enzyme disorder in which the body has adequate iron but is unable to incorporate it into hemoglobin. This inability results from the production of ring sideroblasts in the bone marrow instead of normal erythroblasts, the precursors of mature normal red blood cells.

Description

X-linked sideroblastic anemia is one form of congenital sideroblastic anemia (CSA), also known as iron overload anemia or sideroblastosis. There are three other congenital forms of sideroblastic anemia caused by mutations in different genes. All hereditary forms of sideroblastic anemia are very rare disorders with only a few hundred cases reported in the medical literature.

In sideroblastic anemia, iron enters an immature red blood cell called a sideroblast and is not incorporated properly into the hemoglobin molecule (the cell's oxygen carrier). This failure causes iron to accumulate in the mitochondria surrounding the cell nuclei of the sideroblasts. The defective hemoglobin then transports oxygen poorly, resulting in decreased tissue oxygenation. In addition, the buildup of iron in the sideroblast gives the cell nucleus a ringed appearance. A sideroblast that contains five or more iron granules in its mitochondria is called a ring sideroblast. This is the primary sign of sideroblastic anemia.

Children with X-linked sideroblastic anemia typically develop symptoms early in life, most often as early as the first few months or years of life, but sometimes as late as the early adult years. The most common signs of the condition are pale skin, difficulty breathing, dizzy spells, fatigue, and enlargement of the spleen and liver. Sideroblastic anemia is often mistaken for iron deficiency anemia, but tests usually reveal normal or increased levels of iron in the blood.

Another more common type of sideroblastic anemia is called acquired sideroblastic anemia. This condition develops in later life, most often as the result of myelodysplastic syndromes (blood disorders characterized by inefficient production of blood-forming cells in the bone marrow). It can also develop as the result of lead poisoning, alcoholism, or certain antimicrobial medications. Most cases of acquired sideroblastic anemia develop in adult life. The average age of patients with anemia resulting from a myelodysplastic syndrome is 68. Comparatively, acquired sideroblastic anemia resulting from alcoholism or exposure to toxins begins in the mid-fifties. The goal of treatment is the removal of the toxin and may involve therapy for the underlying disorder.

KEY TERMS

Ataxia—Difficulty in coordinating voluntary muscular movements, particularly those involving gait, speech, hand movements, and eye movements.

Chelation therapy (pronounced key-LAY-shun)—A form of therapy in which chelating agents are administered to remove heavy metals from the body. Chelating agents are chemicals that have a special affinity for metal ions.

Erythroblast—The immediate precursor of a normal red blood cell.

Erythrocyte—The scientific name for a normal mature red blood cell. Erythrocytes do not contain cell nuclei.

Ferritin—An intracellular protein that stores iron and releases it in a controlled manner. Ferritin in blood plasma is an indirect marker of the total amount of iron stored in the body.

Heme—The iron-containing molecule in hemoglobin that serves as the site of oxygen binding.

Hemochromatosis—Accumulation of large amounts of iron in the tissues of the body.

Hemoglobin—The protein-iron compound in the blood that carries oxygen to the cells and carries carbon dioxide away from the cells.

Hemosiderin—An iron storage complex found only within cells (not in blood plasma) and

consisting of ferritin, denatured ferritin, and other materials.

Mitochondria (singular, mitochondrion)—Organelles within the cell responsible for energy production.

Myelodysplastic syndrome (MDS)—A bone marrow disorder that can develop into aplastic anemia, requiring bone marrow or stem cell transplantation.

Nucleus—The central part of a cell that contains most of its genetic material, including chromosomes and DNA.

Red blood cells (RBCs)—Hemoglobin-containing blood cells that transport oxygen from the lungs to tissues. In the tissues, the red blood cells exchange their oxygen for carbon dioxide, which is brought back to the lungs to be exhaled.

Ring sideroblast—A sideroblast that contains five or more iron granules in its mitochondria, enough to form a ring surrounding a third or more of the cell nucleus. It is also called a ringed sideroblast.

Sideroblast—An abnormal erythroblast that contains a cell nucleus with iron granules accumulated in mitochondria around the nucleus.

Transferrin—An iron-binding glycoprotein found in blood plasma that controls the level of iron in biological fluids. The serum transferrin level can be used to check for iron deficiency and hemochromatosis.

X-linked sideroblastic anemia

The hereditary form of the disorder is rare. The primary type of inherited sideroblastic anemia was first described in 1945 by Thomas Cooley, a Detroit pediatrician and hematologist. He identified cases of X-linked sideroblastic anemia in two brothers from a family with a six-generational history of the inherited disease. The genetic abnormality that causes X-linked sideroblastic anemia was identified almost 40 years later. Identification has aided diagnosis of this disorder.

X-linked sideroblastic anemia is caused by a mutation in the *ALAS2* gene at Xp11.21, which codes for an enzyme called erythroid ALA-synthase. This enzyme is necessary for the first step in the production of heme, the iron-bearing molecule in hemoglobin. Some patients have a mutation in the *HFE* gene, which encodes a protein that regulates the amount of iron

absorbed from the diet, in addition to the mutation in the *ALAS2* gene. Those who have mutations in both genes develop a more severe form of the disorder. This severe form is characterized by the absorption of very large amounts of iron from the diet resulting in hemochromatosis, an iron overload disorder.

Another form of X-linked sideroblastic anemia was identified in 1985 and traced to a mutation in the *ABCB7* gene on the X chromosome at Xq13.3. This form of the disorder is characterized by ataxia (uncoordinated gait and lack or loss of coordination in hands and speech) as well as sideroblastic anemia. However, affected males lack the excessive levels of iron storage in their tissues in adult life that is typically found in patients with the more common form of X-linked sideroblastic anemia. Only a few cases of this form of X-linked sideroblastic anemia have been reported and only males appear to be affected.

Other inherited forms of sideroblastic anemia

There are other inherited forms of sideroblastic anemia, which are also rare. Two rare autosomal recessive forms of inherited sideroblastic anemia occur in both males and females of affected families. One type of autosomal recessive sideroblastic anemia is called pyridoxine-refractory because it does not respond to treatment with vitamin B6. It has been linked to two mutations, one in the *SLC25A38* gene on chromosome 3 at 3p22.1 and the other in the *GLRX5* gene on chromosome 14 at 14q32.13.

The other type of sideroblastic anemia inherited in an autosomal recessive pattern is called pyridoxine-responsive because affected individuals do respond to treatment with vitamin B6. As of 2015, this form of congenital sideroblastic anemia has not been traced to a specific gene, but researchers have found that it is not inherited in an X-linked pattern.

Autosomal dominant inheritance has also been reported. Also, Pearson's syndrome, an inherited disorder caused by abnormal mitochondria, is sometimes called sideroblastic anemia with marrow cell vacuolization and exocrine pancreatic dysfunction.

It is likely that other syndromes in which congenital sideroblastic anemia coexists with other disorders will be identified. In 2013 and 2014, a team of researchers in Belgium, Canada, France, Portugal, the United Kingdom, and the United States reported on a syndrome in which sideroblastic anemia is combined with immunodeficiency, fever, and developmental delay (SIFD). The disorder has been linked to a mutation in the *TRNT1* gene.

Genetic profile

Hereditary sideroblastic anemia is most commonly inherited as an X-linked recessive trait, although some rare forms are inherited in an autosomal recessive pattern.

Typical genetic transmission of X-linked disorders

The following concepts are important to understanding the inheritance of an X-linked disorder. All humans have two chromosomes that determine their gender. Females have an XX pattern; males have XY. X-linked recessive, also called sex-linked, inheritance affects the genes located on the X chromosome. It occurs when an unaffected mother carries a disease-causing gene on at least one of her X chromosomes. Because females have two X chromosomes, they are usually unaffected carriers. The X chromosome that does not have the disease-causing gene compensates for the X chromosome that does. For a woman to show symptoms of the disorder, both X chromosomes must have the disease-causing gene. That is

why women are less likely to show such symptoms than males. However, women with one inactivated X chromosome are often symptomatic. In fact, two families with X-linked sideroblastic anemia that appeared in female as well as male members were reported in 1962 and 1965 respectively.

If a mother has a female child, the child has a 50% chance of inheriting the disease gene and being a carrier who can pass the disease gene on to her sons. On the other hand, if a mother has a male child who inherits the disease-causing gene, he will be affected and has a 100% chance of passing the mutated gene on to his children. Because the gene is defective and there is no normal gene in a male with a standard XY chromosome pattern, the singular flawed gene is expressed.

Demographics

X-linked sideroblastic anemia occurs in young men and in some young women with an inactivated X chromosome. It may be seen in maternal uncles and male cousins of men with the disorder. Although the disorder is rare, it has been found in families from different countries and ethnic groups, including African American, Dutch, Italian, Korean, and Japanese families as well as Caucasian Americans. There is no evidence as of 2015 that X-linked sideroblastic anemia is more common in some racial or ethnic groups than in others.

Autosomal recessive forms of the disease may occur in both men and women.

Hereditary sideroblastic anemia affects patients in all age groups. It is most likely to be diagnosed during the first three decades of life, especially during adolescence. However, it has been first diagnosed in patients over 70 years old.

Signs and symptoms

General weakness, fatigue, dizziness, and difficulty breathing are associated with the disorder. Exertion may cause chest pains similar to angina.

The mucous membranes and the skin of the hands and arms of affected patients may be pale, possibly with a lemon-yellow cast. Subcutaneous bleeding may occur, causing a brownish-red discoloration.

Excess iron accumulation, known as hemochromatosis, accumulates over years in the bone marrow, liver, heart, and other tissues. This progressive deposition of toxic iron may result in an enlarged spleen or liver, liver disease, diabetes, impotence, arthritic signs, and heart disease, particularly cardiac arrhythmia.

Diagnosis

Diagnosis of X-linked sideroblastic anemia can be made through an examination of bone marrow aspirate. Ring sideroblasts are visible under microscopic examination of bone marrow when Prussian blue staining is used. The disorder can also be diagnosed by molecular genetic testing, either sequence analysis of the entire coding region or deletion/duplication analysis.

A blood test can indicate the presence of sideroblastic anemia. Indicative laboratory results of an iron panel test include:

- High levels of serum iron, serum ferritin, and transferrin iron saturation.
- Low levels of total iron binding capacity and transferrin.
- Normal to high levels of serum transferrin receptor.

Other signs of sideroblastic anemia include:

- Hemoglobin generally lower than 10.0g/dL.
- Hypochromic (reduced color) cells coexisting with normal cells.
- Stainable marrow and hemosiderin increased.
- Ring sideroblasts visible with Prussian blue staining and observable under microscopic examination of bone marrow.
- Increased width of red cell distribution.
- Normal white blood cells and platelets.

Treatment and management

The main objective in treatment of X-linked sideroblastic anemia is to prevent the development of diabetes, cirrhosis, and heart failure from hemochromatosis.

X-linked sideroblastic anemia often improves with pyridoxine (vitamin B6) therapy. Dosage is 50–200 mg. However, pregnant or nursing mothers may wish to limit intake to 100 mg daily. About 80% of patients respond to treatment with vitamin B6. Phlebotomy (periodic withdrawal of units of blood to prevent hemochromatosis) has also been used successfully to manage X-linked sideroblastic anemia.

In cases of extreme anemia, whole red blood cell transfusion may be required. Repeated whole red blood cell transfusion, however, will contribute significantly to existing iron burden in sideroblastic anemia patients. It will likely require chelation therapy with deferoxamine (Desferal), a drug with iron chelating properties. Deferoxamine binds excess body iron and promotes excretion by the liver and kidneys. It is administered by intravenous infusion from a small portable pump. The pump is worn nine to twelve hours daily, usually at night while

QUESTIONS TO ASK YOUR DOCTOR

- What type of congenital sideroblastic anemia does my child have?
- Is it the X-linked form or an autosomal recessive form?
- Would you recommend bone marrow transplantation?
- What do you expect the chance of improvement to be if pyridoxine is taken?
- What are the most common side effects of pyridoxine?
- What are the early signs of heart failure?
- How often should blood iron levels be monitored?

sleeping. Side effects vary and include pain and swelling at the injection site.

Certain drugs are sometimes associated with treatment of acquired sideroblastic anemia: progesterone, copper chelating drugs, and anti-tuberculosis drugs among others. In other cases, acquired sideroblastic anemia may be secondary to another disorder or disease. Other predisposing causes may be inflammatory disease such as rheumatoid arthritis, cancerous conditions such as leukemia and lymphoma, kidney disorders such as uremia, endocrine disorders such as hyperthyroidism, and metabolic disorders such as porphyria cutanea tarda. With these conditions, it is important to treat the primary disease or disorder in order to reverse the anemia.

Development of leukemia is associated with the acquired form of the disease, often first showing up in the form of a myeloproliferative disorder. These disorders are characterized by abnormal growth of bone tissue and related cells.

Prognosis

Congenital sideroblastic anemia can often be kept in check with regular medical supervision. In a few cases, bone marrow transplantation has been beneficial. Many individuals with X-linked sideroblastic anemia require chronic transfusions to maintain acceptable hemoglobin levels. Over a lifetime, problems related to iron overload, including congestive heart failure and cirrhosis, can become life-threatening issues.

Death can result from hemochromatosis if the disease is untreated or if blood transfusions are inadequate to account for the iron overload.

Xeroderma pigmentosum

Definition

Xeroderma pigmentosum is a rare inherited genetic disease. People with this condition develop skin and eye cancers at young ages because their DNA is extremely susceptible to damage caused by ultraviolet radiation. "Xeroderma" (dry, scaly skin) and "pigmentosum" (freckling and abnormal skin coloring) refer to changes that occur after exposure to sunlight or other ultraviolet radiation.

Description

Xeroderma pigmentosum refers to a group of similar conditions. Each subgroup is designated by a letter or a roman numeral. Xeroderma pigmentosum is also often abbreviated XP. XP A and XP I are the same, as are XP B and XP II, XP C and XP III, etc. There are seven types of xeroderma pigmentosum designated A–G or I–VII. An eighth type of XP is called the "variant" type. XP VIII/XP

H was once a separate subgroup; now it is known to be part of XP D/XP IV.

Each of the eight types of xeroderma pigmentosum has its own DNA defect. However, each section of DNA affected is involved in the same process. These defects affect the body's ability to repair DNA damage, especially DNA damage to the skin caused by exposure to ultraviolet radiation. Sunlight is the most common source of ultraviolet radiation. Everyone's DNA is damaged when it is exposed to sunlight. However, the body has complex and very effective methods to repair the DNA damage. This repair mechanism does not work properly in people with xeroderma pigmentosum. They quickly accumulate damage to their DNA if they are exposed to ultraviolet radiation. Cumulative DNA damage leads to cancer, especially of the skin and the eyes.

DeSanctis-Cacchione syndrome refers to the combination of xeroderma pigmentosum with intellectual disability, short stature, and other symptoms. Trichothiodystrophy (TTD) is sometimes caused by the same DNA change that causes XP D and, rarely, XP B. People with TTD also have brittle hair and nails, physical retardation, and intellectual disability.

Genetic profile

Xeroderma pigmentosum is inherited as an autosomal recessive condition. Everyone inherits one set of genetic material from each parent. People with xeroderma pigmentosum inherited one nonfunctional XP gene from each parent. Their parents have one normal gene and one abnormal gene (of that particular pair); they are called "carriers." Carriers do not have the autosomal recessive conditions because the normal gene in the pair protects them. Two carrier parents have a one in four chance with each pregnancy to have an affected child. A person with xeroderma pigmentosum will have an

Dr. Sulamita Chaibub assists Djalma Antonio Jardim who has xeroderma pigmentosum. (Eraldo Peres/AP Images)

Xeroderma Pigmentosum: pedigree analysis chart (Gale)

affected child only if the child's other parent is a carrier or affected with XP.

The genetics of xeroderma pigmentosum are a bit complicated. The genetic defect in seven of the subgroups has been identified. Each subgroup (A–G) has its own abnormal gene. Each person with xeroderma pigmentosum has a particular subtype, which is associated with one specific abnormal gene. For example, a person with XP type A has no normal XP A gene but does not have XP type B and does not have the abnormal genes associated with XP type B. The genes for types A, B, C, D, E, F, and G are on chromosomes 9, 2, 3, 19, 11, 16, and 13, respectively. The gene for the “variant” type is on chromosome 6. If two people with different forms of xeroderma pigmentosum had a child, the child would not have xeroderma pigmentosum. But if two people with the same type of xeroderma pigmentosum had children, all of the children would also have xeroderma pigmentosum.

This discussion involves two different types of DNA changes. The first DNA change is the change that the person with xeroderma pigmentosum inherits from both parents. This change (mutation) affects the repair enzymes and is present in every cell in the person's body. The second type of change discussed is additional DNA

mutations that result from exposure to ultraviolet radiation. Since the skin and eyes are commonly exposed to ultraviolet radiation that damages DNA and since the body's repair system is not working, people with this condition have a high rate of mutation in the exposed organs. These mutations often manifest themselves as cancers—abnormal, uncontrolled growths. Thus, it is the combination of genetic defect and environmental exposure that causes the manifestations of this disease. The first DNA change would not be nearly as problematic if it did not predispose the person with it to accumulate many additional DNA mutations.

Demographics

Xeroderma pigmentosum occurs in every ethnic group, and it occurs equally in men and women. Approximately 1 in 1,000,000 people in the United States have xeroderma pigmentosum. Approximately 1 in 22,000 Japanese individuals have xeroderma pigmentosum. The most common types are A, C, D, and the variant type.

Signs and symptoms

People with xeroderma pigmentosum have photosensitive skin. This means that their skin is hypersensitive to the effects of sunlight. Development of cancer at a young age

KEY TERMS

Autosomal—Relating to any chromosome besides the X and Y sex chromosomes. Human cells contain 22 pairs of autosomes and one pair of sex chromosomes.

Cancer cells—These cells have characteristics that distinguish them from normal cells and non-cancerous cells; they are threatening, harmful, and resistant to treatment.

Carcinoma—Any cancer that arises in the epithelium, the tissue that lines the external and internal organs of the body.

Chromosome—A microscopic thread-like structure found within each cell of the body and consisting of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Changes in either the total number of chromosomes or their shape and size (structure) may lead to physical or mental abnormalities.

Deoxyribonucleic acid (DNA)—The genetic material in cells that holds the inherited instructions for growth, development, and cellular functioning.

Malignant—A tumor growth that spreads to another part of the body, usually cancerous.

is the most serious consequence. The eyes are also affected. Some people with xeroderma pigmentosum are affected intellectually, but not all. The symptoms a person will have are somewhat predictable based on which mutation he or she has.

Cutaneous symptoms

Skin manifestations usually begin in infancy. Early effects of skin exposure to minimal ultraviolet radiation include acute sunburn, blistering, freckles, increased or decreased pigment, birthmark-like spots, inflammation, dryness, and rough spots. The face, hands, neck, and arms are more severely affected because of increased sun exposure. Multiple scars may develop. The skin is normal at birth.

The average age at which people with xeroderma pigmentosum develop the first skin cancer is eight years. The risk to develop skin cancer is increased 1,000 times over the risk of the general population. A cell accumulates multiple abnormalities in its transition from a normal cell to a cancer cell. Cancers that occur frequently in people with xeroderma pigmentosum include squamous cell carcinoma, basal cell carcinoma, and malignant melanoma. Basal cell cancers are malignant and, if untreated, are characterized

by relentless local invasion but not metastasis elsewhere in the body. Squamous cell cancers are also malignant and, like basal cell carcinomas, tend to be local, although they are occasionally capable of metastasis. Malignant melanoma, as the name implies, is also malignant, but it is much more aggressive than either basal cell or squamous cell cancers of the skin. It is especially threatening because, if not diagnosed and treated early, it commonly will spread to internal organs and can be fatal. Cancer may occur on the eyes, lips, and tongue.

Ocular symptoms

Most people with xeroderma pigmentosum also have extremely light-sensitive eyes. Their eyes easily become irritated, red, and swollen. Abnormal growths may appear. Cataracts may occur at an unusually young age.

Other symptoms

The other symptoms associated with xeroderma pigmentosum are variable. Many people who are affected only have eye and skin manifestations. Mental deterioration may occur; when it does, it usually worsens over time. Neurological symptoms are not believed to be associated with sun exposure. Some people have one or a combination of deafness, poor reflexes, lower intelligence, or spasticity (in addition to ocular and cutaneous symptoms).

Diagnosis

Xeroderma pigmentosum may be suspected based on a person's history of skin changes that occurred after minimal exposure to sunlight. The diagnosis is confirmed by a blood test or a skin test. The skin or blood cells are sent to a specialty laboratory. Studies are performed to determine whether the cells are hypersensitive to ultraviolet radiation. Scientists may examine whether abnormal changes can be seen in the chromosomes. The type of xeroderma pigmentosum may be determined by genetic studies or other specialized studies.

Genetic testing for xeroderma pigmentosum is complicated because there are eight different genes involved. Genetic tests are usually very specific, looking for a change in one gene. To confirm a diagnosis of xeroderma pigmentosum by DNA testing, scientists must look for multiple changes in eight different genes.

Prenatal diagnosis may be possible, especially if genetic studies have already been performed on an affected sibling and the parents.

Treatment and management

The only treatment for xeroderma pigmentosum is avoiding harmful exposure to ultraviolet radiation and

QUESTIONS TO ASK YOUR DOCTOR

- How can avoidance of UV light best be accomplished?
- What are the risks and benefits of treatment with medication?
- How often should my child be screened for abnormal growths?
- Which family members should undergo genetic testing?

treating/removing growths as they occur. The DNA damage caused by exposure to ultraviolet light accumulates over time and the resulting DNA damage is irreversible.

Life is changed dramatically when a family member has xeroderma pigmentosum. Extreme measures must be taken to completely avoid exposure to the sun. Preventative measures include sunglasses, tightly woven long-sleeved clothing, wide brim hats, sunblock, and protective window coverings (at home, in the car, and at school). Children do not play outside during the day. All sources of ultraviolet radiation are avoided, even exposure to certain light bulbs. These precautions are critical to survival. Levels of ultraviolet radiation at home and at school can be measured with special instruments. Abnormal skin growths and other symptoms are treated/removed as they arise. Regular visits are made to the eye doctor, dermatologist, and neurologist. Often psychosocial support is also helpful.

Treatments that would deliver DNA repair proteins into the skin of affected patients are under investigation. Some people with xeroderma pigmentosum may be offered other types of medication, like isotretinoin. The dermatologist weighs the benefit of prescribing a medication against the side effects associated with that medication.

Because our bodies have different mechanisms for fixing different forms of DNA damage, people with xeroderma pigmentosum are most susceptible to DNA damage by ultraviolet radiation. Some other exposures have been associated with the type of DNA damage caused by ultraviolet radiation. Therefore, people with xeroderma pigmentosum should also avoid exposure to tobacco and certain other drugs.

Prognosis

Life expectancy is significantly reduced due to morbidity associated with the cancers. Researchers have not

determined how effective preventative measures are (e.g., avoidance of ultraviolet radiation).

In the 1990s scientists discovered a great deal about DNA repair mechanisms and about the genes associated with xeroderma pigmentosum. The range of symptoms associated with each type have been better defined. The media has also been interested in XP, giving it more attention than is typical for such a rare condition. Advocates in the XP community have developed helpful resources for other affected families, such as Camp Sundown.

XMEN

Definition

XMEN is a rare genetic disorder classified as a primary immune deficiency disease or PIDD. The term "primary" means that the immune disorder arises by itself and

KEY TERMS

B cells—Lymphocytes that originate in the bone marrow and make antibodies in response to antigens.

CD4+ cells—A type of T cell that secretes small proteins (called cytokines) that regulate the body's active immune response to infections.

CD8+ cells—A type of T cell that kills cancer cells, cells infected with viruses, or cells that are damaged in other ways. CD81 cells are also known as cytotoxic T cells, killer T cells, and cytolytic T cells.

Epstein-Barr virus (EBV)—A human herpesvirus (HHV-4) that causes infectious mononucleosis and is associated with certain types of cancer and complications of HIV infection.

Latency—The ability of some viruses to remain dormant in the body after the acute infection has subsided.

Loss-of-function mutation—A genetic mutation in which the protein encoded by the gene has little or no effectiveness.

Lymphocyte—Any of three types of white blood cells that play an important role in the immune system. They include T cells, B cells, and natural killer (NK) cells.

Lymphoma—A general term for a group of cancers that affect the immune system; they develop from lymphocytes, cells in the lymphatic system.

Lymphopenia—A condition marked by an abnormally low level of lymphocytes in the blood.

Neoplasia—An abnormal proliferation of cells, which results in an abnormal mass of tissue known as a neoplasm.

Neutropenia—An abnormally low level of neutrophils in the blood. Neutrophils are the most common type of circulating white blood cells and are the first line of defense in the body's response to inflammation.

Primary immune deficiency diseases (PIDDs)—A group of rare genetic disorders caused by inherited defects in specific cells of the immune system. XMEN is one of about 200 known PIDDs.

Splenomegaly—Enlargement of the spleen.

T cells—A type of lymphocyte that plays an important role in cell-mediated immunity. There are several different subtypes of T cells, including helper (CD41) cells and cytotoxic (CD81) cells. T cells are so called because they mature in the thymus gland.

is not secondary to another disease, drug treatment, or exposure to environmental toxins. The acronym XMEN stands for “X-linked immune deficiency with magnesium defect, Epstein-Barr virus (EBV) infection, and neoplasia.” The word “neoplasia” in the name of the disorder refers to the abnormal proliferation of cells characteristic of lymphomas and other cancers.

Description

XMEN is a genetic disorder that affects only males. It is characterized by severe recurrent upper respiratory and ear infections, persistent EBV activity, an abnormally low number of T helper lymphocytes (also called CD4+ lymphocytes), defective activation of another type of T cell (CD8+ T cells), and eventual development of lymphomas, which are cancers that develop in cells of the immune system. The disorder was identified in 2011 by a team of researchers at the National Institute of Allergy and Infectious Diseases (NIAID), and much is still unknown about it. Its discovery has, however, led to a new understanding of the role of magnesium in cellular signaling within the human immune system.

Genetic profile

XMEN, as its name indicates, is an X-linked disorder, which means that it is sex-linked. The gene associated with XMEN, the *MAGT1* gene, is located on the X chromosome, which is a sex chromosome. Only males are affected by X-linked disorders because they have only one X chromosome and will develop the disorder if they inherit an X chromosome with the defective gene from the mother. Females, who have two X chromosomes, are carriers of X-linked disorders but will not develop symptoms because their second X chromosome is usually normal. Another characteristic of X-linked disorders is that fathers with X-linked disorders cannot pass them on to their sons.

The specific gene associated with XMEN, the *MAGT1* gene, is located on the long arm of the X chromosome at Xq21.1. The gene codes for a protein that is a magnesium transporter, which moves magnesium ions into T cells—particularly the CD8+ T cells, which help to control infections like EBV infections. CD8+ T cells normally take in magnesium when they detect the presence of a virus or other foreign invader. In addition to the CD8+ T cells, some researchers think that the

magnesium transporter protein also plays a role in the production of CD4+ T cells in the thymus gland.

The mutation in the *MAGT1* gene that causes XMEN is a loss-of-function mutation, which means that it results in insufficient amounts of the magnesium transporter protein. This lack, in turn, reduces the amount of magnesium that enters the T cells, preventing effective activation of the CD8+ cells. When these cells are not activated, they cannot attack the Epstein-Barr virus, and the uncontrolled presence of EBV in the patient's body increases his risk of developing lymphoma. In regard to the CD4+ cells, the insufficiency of the magnesium transporter protein means that the thymus will produce too few of these cells, which accounts for the low number of CD4+ T cells in patients diagnosed with XMEN.

Demographics

XMEN is a very rare disorder, with only seven cases reported in the medical literature as of 2015, and an eighth diagnosed in Canada that year. One patient, a 45-year-old man, was diagnosed only after his death. Because the disorder has been identified only recently and so few cases have been diagnosed, very little is known about the frequency of XMEN worldwide or whether it is more common in some racial or ethnic groups than others.

Signs and symptoms

The signs and symptoms of XMEN include a history of recurrent ear, sinus, and respiratory infections, and the persistence of infections caused by the Epstein-Barr virus (EBV). This virus, which causes infectious mononucleosis and is associated with such cancers as Burkitt lymphoma and Hodgkin's lymphoma, is also a common cause of childhood infections. About 50% of five-year-olds and 90% of adults in the United States have been infected with EBV. In people with a normal immune system, the virus remains latent within the B cells of the immune system for the rest of the patient's life after the acute infection subsides. In patients with XMEN, however, the EBV virus does not enter latency but remains active; the EBV infections do not resolve but persist, increasing the patient's risk of developing lymphoma as an adult.

Other symptoms associated with XMEN include splenomegaly (enlargement of the spleen), recurrent diarrhea, and other infections associated with a weakened immune system, including pneumonia, streptococcal throat infections, and whooping cough (pertussis).

QUESTIONS TO ASK YOUR DOCTOR

- Have you ever treated a patient with a primary immune deficiency disease?
- Have you ever referred a patient to the Primary Immune Deficiency Clinic at NIAID?
- Do you think that researchers will develop an effective therapy for XMEN in the near future?

Diagnosis

The diagnosis of XMEN is based on observation of the patient's symptoms, particularly a history of recurrent ear, sinus, or other upper respiratory infections. The patient's spleen may be sufficiently enlarged to be felt during the doctor's examination of the patient's abdomen. Laboratory test results suggest XMEN includes the presence of a large number of cells infected with the EBV virus, a very low number of CD4+ T cells (CD4+ lymphopenia), a low ratio of CD4+ T cells to CD8+ T cells, and mild neutropenia (a low number of neutrophils in the blood).

The diagnosis can be confirmed by molecular genetic testing for the defective *MAGT1* gene. As of 2015, testing for this gene was available at the Primary Immune Deficiency Clinic at the National Institute of Allergy and Infectious Diseases (NIAID) and at the Molecular Genetics Laboratory of the Cincinnati Children's Hospital Medical Center in Ohio.

Treatment and management

Treatment options for XMEN were limited as of 2015. Bone marrow transplantation is one possible treatment for the disorder, but its effectiveness is unknown. Another treatment that shows promise is supplementation with an oral form of magnesium threonate, a compound that appears to be safe for long-term use provided that the therapy is carefully supervised by a physician. Further research is needed, as it is not yet known whether magnesium supplements will prevent the development of lymphoma in patients with XMEN. Patients suspected of having XMEN should consult the Primary Immune Deficiency Clinic at NIAID for an examination, diagnosis, and treatment recommendations.

Prognosis

The prognosis of XMEN is uncertain, in part because so little is known about this disorder and whether current treatment options will slow or prevent progression to lymphoma.

XO syndrome see **Turner syndrome**

XXXX Syndrome

Definition

XXXX syndrome is a genetic disorder in girls in which they have four X chromosomes rather than two. Also known tetra-X, tetrasomy X syndrome, and 48-X

syndrome, the condition may cause lowered intelligence, increased height, speech and language disorders, and infertility.

Description

Humans normally have 46 chromosomes, 23 from each parent. In XXXX syndrome, girls are born with 2 extra chromosomes, for a total of 48. Symptoms range from mild to severe. Some children with the disorder are never able to lead independent lives, although others play sports and attend college. The physical characteristics may be slight and not readily observable. Health problems associated with the syndrome also range from quite mild to more severe. XXXX syndrome was first reported in the medical literature in 1961. Research on XXXX syndrome has been limited, but there has been more interest in the topic in recent years.

Girls with XXXX syndrome generally do not have the obvious appearance of a chromosomal disorder. Their faces appear normal, and if differences are noted they are usually minor. The features that they may possess include epicanthal folds (creases next to the inner corner of the eye), eyes that may slant upward, and extra folds on the back of their neck. Their eyes may be widely spaced apart.

The speech and language disorders associated with XXXX syndrome are believed to be at the root of some of the behavioral problems described with this population. While many of the girls are described as pleasant and easy going, they also may have issues with anger management, mood swings, and shyness. Some girls experience psychiatric problems such as bipolar disorder and depression. Social difficulties have been reported among this group, although this issue is not consistently found among girls with XXXX syndrome.

Because there are so few cases in the world, studies are based on relatively small numbers. There are reports of four women with XXXX syndrome having a total of seven children. All were normal babies—a mixture of boys and girls—with the exception of one stillbirth and one baby born with Down syndrome.

Risk factors

XXXX syndrome is extremely rare. In a rare number of cases, mothers of XXXX syndrome girls have been found to have an extra X chromosome in some cells.

Genetic profile

XXXX syndrome occurs when a girl inherits either three X chromosomes from her mother and one X chromosome from her father, or when she inherits both extra

KEY TERMS

Epicanthal fold—A wrinkle in the skin extending from the nose up to the eyebrow and sometimes associated with genetic anomalies.

Renal—Pertaining to the kidney.

chromosomes from her mother. It is believed that, in the formation of the mother's egg, errors in cell division cause the egg to contain multiple X chromosomes rather than only one. In some cases it is believed that the mother's child may first develop five X chromosomes, but one chromosome dies and the baby is left with four. XXXX syndrome can also be caused during conception, if there are errors in cell division at that time or if the mother carries an extra X chromosome in some of her cells.

An environmental cause for XXXX syndrome has not been found, and it is believed that neither environment nor maternal lifestyle causes this condition.

Demographics

XXXX syndrome only affects girls, and is extremely rare. It is estimated that there are 100 girls and women in the world with the condition. A Penta-Tetra X registry has been established in the United Kingdom. Sex chromosome disorders in which a baby is born with 47 to 49 chromosomes include a variety of conditions affecting boys and girls, and occur in 1 out of 400 births. There may be a number of cases of girls with this disorder who have not been diagnosed.

Signs and symptoms

The clinical symptoms of XXXX syndrome vary from one girl to the next. Some have milder symptoms, while others face more severe issues. The following is a list of symptoms that appear to be more prevalent with this population:

- Delayed physical development (mild)
- Delayed speech development
- Difficulty learning (mild to moderate)
- Tall stature (in some cases)
- Tendency toward stress
- Higher risk of dysfunctioning ovaries
- Higher incidence of respiratory infections (during younger years) than most girls of same age
- High arched palate

- Epicanthal folds, upward slanted eyes, and extra folds in the back of the neck
- Heart conditions of varying levels (affects approximately one-third of the girls)
- Kidney disorders
- Joint problems

As babies, girls with XXXX syndrome exhibit delays in physical development such as sitting and walking. Some of the girls experience weaker muscle tone and abnormally loose ligaments, factors that contribute to such delays. However, it is important to note that when the children gain the ability to walk and run, girls with XXXX syndrome can be quite active. They typically jump and play, and by their teenage years enjoy swimming and other sports.

Kidney disorders range from mild to severe. In some cases, the kidneys are fused together; in others, the girl is born with only one kidney. Because of a defect in valves regulating urine flow that may occur, there may be difficulty with the flow of urine from the kidneys to the bladder.

The palate may be highly arched, leading to a susceptibility toward ear infections as bacteria moves readily from the mouth to the ears. It is important that hearing is monitored to determine if hearing loss occurs, and it is also essential to monitor and treat ear infections promptly. The arch of the palate may also lead to problems with teeth; some girls experience teeth that erupt too early, while others have a delay in tooth eruption.

Approximately half of the girls experience normal menstruation; the other half lack menstruation (or have irregular menstruation) as well as underdeveloped sexual features.

Approximately one-third of the girls may have varying degrees of heart conditions, ranging from murmurs to holes in either the septum (dividing partition) of the atria (upper chambers) or ventricles (lower chambers).

Problems with joint structure and movement seem to be an issue with this population. Some girls suffer with joints that are stiff or even fused, while others experience joints with hyper-rotation.

At birth, girls with XXXX syndrome are of slightly lower weight, with an average birth weight of 6.2 pounds. The girls tend to eat well and grow at a healthy pace; in fact, they tend to be tall children. Researchers believe it is possible that the extra chromosome adds to height. Another potential rationale for the increase in height among these girls is the lower levels of estrogen secretion. The range in height, although the sample is small because of the rarity of this disorder, is 5 foot 3 inches to 6 foot 2 inches.

QUESTIONS TO ASK YOUR DOCTOR

- Is my child considered to have a mild or severe case of XXXX syndrome?
- What supportive measures can I take to enhance my daughter's life?

In 1979, researchers at the University of California at Los Angeles reported on the first incident of a girl with XXXX syndrome lacking ovaries. The 16-year-old girl had a uterus and fallopian tubes but no ovaries. Consistent with the syndrome, the girl had intellectual disability, although mild, as well as other mild characteristics associated with the condition.

The disorder affects intellectual development. A “rule of thumb” is that intelligence decreases 10–15 points for every extra chromosome. The average intelligence quotient (IQ) for the girls ranges from 60 to 80. While some girls attend schools with supportive environments, others go on to college. It has been said that the most representative features of the syndrome are learning disability and delay in speech development. On average, they learn to speak at age three years. Issues with complex speech and vocabulary may persist into the upper grades.

Diagnosis

Examination

The clues that a baby has XXXX syndrome may be subtle at first. Symptoms of a chromosomal disorder, including epicanthal folds, may be present, but slight. In many cases, the baby's low birth weight, failure to meet developmental milestones, and sometimes the lack of muscle tone ultimately prompt the pediatrician to suggest genetic testing. The diagnosis often comes after parents face an extended period during which their baby does not perform activities that are appropriate for her age.

Tests

Genetic testing may be performed on body tissues such as blood or skin.

Procedures

XXXX syndrome may be diagnosed with prenatal chromosome testing such as chorionic villus sampling or amniocentesis.

Treatment and management

XXXX syndrome cannot be prevented. Regular medical testing throughout the girl's life, however, plays an important role in preventing complications of the syndrome, such as serious heart or kidney issues.

It is important to monitor kidney function because some girls have defects in the renal system. Kidney ultrasounds are recommended, as frequent infections of the kidney may impair kidney function later in life.

Some girls may require ear tubes if they experience recurrent infections.

Prognosis

Intellectual disability of varying degrees limits the chance of an independent life for those who have more severe forms of XXXX syndrome. Girls with mild intellectual disability may live independently, but others must live in a setting that offers supervision and support.

Girls who have XXXX syndrome are more likely to have a daughter with the disorder; therefore, genetic counseling is strongly suggested if pregnancy is considered.

Infections caused by this syndrome may lead to serious consequences later in life. Infections of the ears, due to the high palate, may lead to deafness. Kidney infections may lead to high blood pressure and kidney damage.

Hormonal problems may also create problems later in life. Low estrogen production can hasten osteoporosis, making the girls and women more susceptible to bone fractures.

XXXXX syndrome

Definition

XXXXX syndrome (also called pentasomy X, penta X syndrome, or 49,XXXXX) is a rare genetic disorder in girls in which they have five X chromosomes rather than two. The disorder may cause lowered intelligence, physical deformities, and psychological problems.

Description

XXXXX syndrome is an extremely rare chromosomal condition affecting only girls. Researchers first described the condition in the *Journal of Pediatrics* in 1963. Seventeen years later, there had been only 12 cases noted in professional scientific publications. As of 2015, only 26 cases had been reported in medical journals.

During the 1960s and 1970s, there was a burst of scientific research in XXXXX syndrome and related disorders. After that time period passed, research on the disorder became rare; however, in the early 2000s, scientific interest in XXXXX syndrome grew. In 2009, the National Institutes for Health in Bethesda, Maryland, was accepting participants for a study of XXXXX syndrome. The study hoped to determine the effect of the disorders on the development of the brain, and whether brain imaging methods can identify the biological features of the brain that are associated with the disorders.

The most common characteristics of this syndrome are short height, short neck, round face, microcephaly, intellectual disability, fifth finger clinodactyly, and heart and kidney defects.

Infants with XXXXX syndrome share a number of characteristic features such as a round face, flat nose bridge, deformities of the ears, and upward slanting eyes. The girls also might have mild to severe intellectual disability. As a general rule there is a 10- to 15-point reduction in Intelligence Quotient (IQ) for each extra sex chromosome. Additionally, the chance of intellectual disability and dysmorphism rises with each extra sex

KEY TERMS

Clinodactyly—Curving of the finger to the left or right.

Epicanthal folds—Crease in the skin extending from the nose to the eyebrow.

Microcephaly—Abnormal smallness of the head; it often is associated with intellectual disability.

Missegregation of chromosomes—The faulty segregation of chromosomes into the appropriate daughter cells, in either mitosis (cell division) or meiosis (reproductive cell [sperm or egg] production).

chromosome. In the case of XXXXX syndrome, girls have three extra X chromosomes. Scientists believe that the presence of one extra X chromosome in a mother creates a slightly higher risk of having a daughter with XXXXX syndrome. Only females are at risk.

Genetic profile

XXXXX syndrome is caused by an aneuploidy (the presence of extra chromosomes) of the X chromosome. XXXXX syndrome is believed to be the result of a non-disjunction error in cell division during the process of chromosome splitting within the mother's ova that causes missegregation of the chromosomes. As a result of this error, the ovum contains more than 23 chromosomes. The occurrence of defects in the chromosome segregation during meiosis can result in several forms of chromosome duplication. Additional sex chromosome missegregation defects include the trisomy, tetrasomy, or other karyotypes that can occur in both males and females.

Demographics

XXXXX syndrome is very rare. It is estimated that the syndrome is present in 1 out of 85,000 female births, though this is considered to be an overestimation. The condition only affects girls.

Signs and symptoms

The most common symptoms associated with XXXXX syndrome include growth delays before birth and a failure to grow and gain weight following birth. The developmental deficiencies include short height, short neck, round face, microcephaly, moderate to severe intellectual disability, fifth finger clinodactyly, and heart and kidney defects.

Girls with XXXXX syndrome may exhibit any number of classic signs, such as:

- Developmental delays: physical and intellectual delays are possible
- Microcephaly (abnormal smallness of the head)
- Facial features: round face, upward slanting eyes, wide-set eyes, epicanthal folds, ear and tooth abnormalities, and short neck length
- Musculoskeletal: deformities in the elbow, foot (club foot may be present), overlapping toes, and larger space between first and second toes, fifth finger clinodactyly, weak muscle tone (hypotonia)
- Heart: defects in the heart may be present (atrial septal defect, ventricular septal defect, patent ductus arteriosus)
- Kidneys: horseshoe kidneys

Psychiatric symptoms have been described in girls with XXXXX syndrome. It is believed that the psychiatric symptoms are related to the presence of extra chromosomes.

In 1980, one case was reported in which a three-year-old girl with XXXXX syndrome had one underdeveloped kidney and was missing one ovary. The present ovary was believed to function normally, suggesting to researchers that the girl would be able to reproduce.

In 1999, the first case of XXXXX syndrome along with hyper IgE syndrome (HIE) was reported in a ten-year-old girl. The girl experienced a history of eczema as well as recurrent pneumonia and staphylococcal abscess in addition to the features commonly associated with XXXXX syndrome. This was the first case in which the presence of these two distinct chromosome disorders appeared together in one individual.

The syndrome has also been described in the medical literature as having similar attributes to Down syndrome.

Diagnosis

Diagnosis of XXXXX syndrome is usually made during childhood, as the symptoms become more pronounced. Diagnosis is confirmed through karyotyping, a chromosome number assessment test, and may include blood or skin tests. As of 2015, five cases had been diagnosed through prenatal testing procedures. The syndrome, if present, will appear on chorionic villus sampling or amniocentesis. The symptoms of XXXXX syndrome become more apparent as the girl progresses through early childhood. Ultimately, suspicions lead the parents and health care practitioner to seek testing.

Treatment and management

Girls with XXXXX syndrome experience medical conditions that range from mild to severe. The level of

QUESTIONS TO ASK YOUR DOCTOR

- What are my chances of having another child with XXXXX syndrome?
- How will I know if my daughter's condition is a mild or severe form of XXXXX syndrome?

severity dictates the treatment needed. If medical conditions such as atrial septal defect are present, heart surgery may be needed.

Because the syndrome is associated with poor muscle tone and speech abnormalities, physical, speech, and occupational therapies are recommended.

Atrial septal defect

If a child has an atrial septal defect, treatment to close the hole in the septum may be necessary. In the past, open-heart surgery was the only surgical option; however, methods of closing certain types of holes without surgery have been developed. Parents will need to discuss the options with their child's physician.

Ventricular septal defect

A ventricular septal defect, which may occur, is a hole in the membrane that separates the two ventricles, which are the lower chambers of the heart. Treatment depends on the size of the hole. If it is small, it may not require any treatment. If the hole is large, open heart surgery may be required. If serious symptoms develop in the first months of life, surgery on the baby may be essential. If the symptoms are mild, surgery may be delayed a few years. Surgery involves closing the hole with a patch.

Prognosis

There is no way to prevent XXXXX syndrome. The long-term prognosis depends on the severity of the syndrome in the individual girl. A more positive prognosis is generally associated with earlier diagnosis, sound treatment for medical conditions, and modalities such as occupational, physical, and speech therapies. If cardiac defects are present, treatment for such defects improves the prognosis.

XXY syndrome

Definition

XXY syndrome is a chromosome disorder that affects males. Males with this disorder have an extra Y chromosome.

Description

The XYY syndrome was previously considered the *super-male* syndrome, in which men with this condition were thought to be overly aggressive and more likely to become criminals. These original stereotypes came about because several researchers in the 1960s found a high number of men with XYY syndrome in prisons and mental institutions.

These original observations did not consider that the majority of males with XYY syndrome were not in prisons or mental institutions. Since then, broader, less biased studies have been done on males with XYY syndrome. Though males with XYY syndrome may be taller than average and have an increased risk for learning difficulties, especially in reading and speech, they are not overly aggressive. Unfortunately, some text books and many people still believe the inaccurate stereotype of the *super-male* syndrome.

Scanning electron micrograph of human chromosomes, showing one X and two Y chromosomes, or XYY syndrome. People with this disorder are slightly taller and may have learning disabilities. (Biophoto Associates/Science Source)

Genetic profile

Chromosomes are structures in the cells that contain genes. Genes are responsible for instructing our bodies how to grow and develop. Usually, an individual has 46 chromosomes in each cell, or 23 pairs. The first 22 pairs are the same in males and females, and the last pair, the sex chromosomes, consist of two X chromosomes in a female and an X chromosome and a Y chromosome in a male.

XYY syndrome occurs when an extra Y chromosome is present in the cells of an affected individual. People with XYY syndrome are always male. The error that causes the extra Y chromosome can occur in the fertilizing sperm or in the developing embryo.

XYY is not considered an inherited condition. An inherited condition usually is one in which the mother and/or father has an alteration in a gene or chromosome that can be passed onto their children. Typically, in an inherited condition, there is an increased chance that the condition will reoccur. The risk of the condition reoccurring in another pregnancy is not increased above the general population incidence.

Demographics

XYY syndrome has an incidence of 1 in 1,000 newborn males. However, since many males with XYY syndrome look like other males without XYY syndrome, many males are never identified.

Signs and symptoms

There are no physical abnormalities in most males with XYY syndrome. However, some males can have one or more of the following characteristics. Males who have XYY syndrome are usually normal in length at

birth, but have rapid growth in childhood, typically averaging in the seventy-fifth percentile (taller than 75% of males their same age). Many males with XYY syndrome are not overly muscular, particularly in the chest and shoulders. Individuals with XYY syndrome often have difficulties with their coordination. As a result, they can appear to be awkward or clumsy. During their teenage years, males with XYY syndrome may develop severe acne that may need to be treated by a dermatologist.

Men with XYY syndrome have normal, heterosexual function, and most are fertile. However, numerous case reports of men with XYY syndrome presenting with infertility have been reported. Most males with XYY syndrome have normal hormones involved in their sperm production. However, a minority of males with XYY syndrome may have increased amounts of some hormones involved in sperm production. This may result in infertility due to inadequate sperm production. The true incidence of infertility in males with XYY syndrome is unknown.

When XYY men make sperm, the extra Y chromosome is thought to be lost resulting in a normal number of sex chromosomes. As a result, men with XYY syndrome are not at an increased risk for fathering children with chromosome abnormalities. However, some men with XYY syndrome have been found to have more sperm with extra chromosomes than what is found in men without XYY syndrome. Whether these men have an increased risk of fathering a child with a chromosome abnormality is unknown.

Men with XYY syndrome usually have normal intelligence, but it can be slightly lower than their brothers and sisters. Approximately 50% of males with XYY syndrome have learning difficulties, usually in language and reading. Speech delay can be noticed in early school years. Males with XYY syndrome may not process information as quickly as their peers and may need additional time for learning.

Males with XYY syndrome have an increased risk of behavior problems. Hyperactivity and temper tantrums can occur more frequently than expected, especially during childhood. As males with XYY syndrome become older, they may have problems with impulse control and appear emotionally immature.

From a psychosocial standpoint, males with XYY syndrome may have low self-esteem due to mild learning disabilities and/or lack of athletic skills due to lack of coordination. Males with XYY syndrome are at risk in stressful environments and have a low ability to deal with frustration.

Men with XYY syndrome are not thought to be excessively aggressive or psychotic. However, because some men with XYY syndrome can have mild learning

KEY TERMS

Amniocentesis—A procedure performed at 16–18 weeks of pregnancy in which a needle is inserted through a woman's abdomen into her uterus to draw out a small sample of the amniotic fluid from around the baby. Either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Cell—The smallest living units of the body which group together to form tissues and help the body perform specific functions.

Chorionic villus sampling (CVS)—A procedure used for prenatal diagnosis at 10–12 weeks gestation. Under ultrasound guidance a needle is inserted either through the mother's vagina or abdominal wall and a sample of cells is collected from around the early embryo. These cells are then tested for chromosome abnormalities or other genetic diseases.

Chromosome—A microscopic thread-like structure found within each cell of the body and consists of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Changes in either the total number of chromosomes or their shape and size (structure) may lead to physical or mental abnormalities.

Embryo—The earliest stage of development of a human infant, usually used to refer to the first eight weeks of pregnancy. The term “fetus” is used from roughly the third month of pregnancy until delivery.

Hormone—A chemical messenger produced by the body that is involved in regulating specific bodily functions such as growth, development, and reproduction.

difficulties and/or have difficulty controlling behavior problems such as lack of impulse control, their actions may lead to criminal behavior if placed in the right environment. It is important to emphasize that this only occurs in a small percentage of men with XYY syndrome. Most men with XYY syndrome are productive members of society with no criminal behavior.

Diagnosis

Most individuals with XYY syndrome (or 47,XYY) go through their entire lives without being diagnosed with this condition. Chromosome studies can be done after birth on a skin or blood sample to confirm the condition.

QUESTIONS TO ASK YOUR DOCTOR

- When should my son be evaluated for a learning disability?
- Do you recommend physical, occupational, or speech therapy?
- Is genetic testing recommended, and on whom?
- What supportive stress-reducing measures should I implement at home?

This syndrome can also be diagnosed coincidentally when a pregnant mother undergoes prenatal testing for other reasons, such as being age 35 or older at the time of delivery. Prenatal tests that can determine whether or not an unborn baby will be affected with 47,XXY are the chorionic villus sampling and amniocentesis procedures. Both procedures are associated with potential risks of pregnancy loss and therefore are only offered to women who have an increased risk of having a baby born with a chromosome problem or some type of genetic condition.

Treatment and management

Treatment and management for most men with XYY syndrome is not indicated. However, early identification and intervention of learning disabilities and/or behavior difficulties is necessary. Speech therapy, physical therapy, and occupational therapy may be helpful for males with XYY syndrome. Also, because males with XYY syndrome are at risk in stressful environments, a supportive and stimulating home life is important.

Prognosis

Most males who have learning disabilities and/or behavior problems due to XYY syndrome have an excellent prognosis. Learning disabilities are mild, and most affected males learn how to control their impulsiveness and other behavior problems. XYY syndrome does not shorten lifespan.

YY syndrome

Definition

The YY syndrome is an unusual disorder in the history of pathology. The underlying genetic condition and cause were discovered before any evidence of the syndrome was observed. YY syndrome was discovered through the study of the diversity in the chromosomes of the chromosome pair 46. While most males have an X and a Y chromosome, some were observed to have an extra Y chromosome. The question then arose: How does the presence of an extra chromosome influence the normal development of the affected male?

The differences that distinguish the YY male are subtle and are usually not seen before the age of ten. Many males grow up without even realizing that they have the YY condition. Most of those affected tend to be taller and thinner than age-related norms. There is some evidence of speech delay and learning disabilities. Although the YY male is more aggressive than average, there is no noticeable increase in behavioral problems.

Description

The YY syndrome is a very mild disorder; it is certainly not considered a disease. It is best to know as early as possible if a boy has it, because the mild learning disabilities and the slight language delay can be accommodated better at a young age. However, most boys realize they have the YY condition only after they have grown taller than their peers in late childhood. Many who have it never know they are YY susceptible.

In the usual fertilization of the egg, the father contributes a sperm with either an X chromosome which determines that the resulting zygote will be female or with a Y chromosome which determines that the resulting zygote will be male. For an unknown reason, in some cases, the Y chromosome in the sperm splits in two before fertilization. The resulting zygote is male with

KEY TERMS

Amniocentesis—A procedure that extracts fluid from the amniotic sac in order that the chromosomes of the fetus can be examined. This test can determine lung maturity and the possibilities of birth defects.

Chromosome—A threadlike linear strand of DNA and associated proteins in the nucleus of eukaryotic cells that carries the genes of an organism.

Fertile—Able to reproduce.

Insemination—The process by which sperm is placed into the female reproductive tract for the purpose of impregnation.

Zygote—The sperm and egg combined to form the initial cell when a new organism is produced by means of sexual reproduction.

two Y chromosomes instead of one. The age of either parent is inconsequential in contributing to this disorder. This condition is not considered to be inherited, as the fathers with YY syndrome do not have sons with YY in any greater frequency than the general population.

The studies documenting the severity of the symptoms constantly note how mild and close to average all of the distinctive differences are. The most notable condition is the tendency to grow very tall earlier than peers and the tendency to be thinner than peers. However, the final height and body weight are still within normal range. Most of these boys have a language delay but eventually catch up to peers. Most have a learning disability but also have normal measured intelligence. They tend to be more aggressive than other boys and like physical activities. However, most adapt to the classroom and behavioral problems are no greater than the normal population. As a group they are distinctive but as individuals few are abnormal.

When the condition was first discovered, there was the assumption that such boys would grow up to be infertile. However, longitudinal studies have concluded that as an adult, the YY male is no less fertile than the general population. However, the semen of a YY male is slightly weak because of the presence of more than average dead sperm.

While this is a very mild disorder, it is beneficial to discover its presence in a young boy. The earlier that it is detected contributes to the sooner that more serious conditions can be ruled out. Furthermore, with appropriate treatment, the boy can overcome the effects of the language delay and learning disability. If the boy is forewarned, he will not become apprehensive when the rapid growth takes place.

Genetic profile

The condition is caused by an unusual split in the Y chromosome of a pre-insemination human sperm that manages to fertilize a human egg. The resulting zygote evolves over nine months of gestation and is born as a male infant with two Y chromosomes instead of one.

Demographics

The prevalence rate in the United States is 12 per 10,000 male births, with the rate for those of African descent being slightly lower. Studies from Norway and Japan suggest similar rates. The condition only affects males.

Signs and symptoms

The symptoms as noted above include unusual height and thinness, language delay, learning disability, and aggressive physical activity. Measured intelligence is within normal limits. The cases of behavioral problems within this population of boys are also within normal limits.

Diagnosis

There are no signs of this disorder at birth. Therefore, there would be no observable sign of this disorder through a prenatal ultrasound. This disorder can be detected through a prenatal amniocentesis; however, analysis of amniotic fluid does not usually look for the signs of YY syndrome.

Most boys are diagnosed with this disorder as a result of parental concerns for language delay or excessive growth. Diagnosis can take place through noting evidence for all of the usual symptoms. However, confirmation of this diagnosis must be done through

QUESTIONS TO ASK YOUR DOCTOR

- How can we help our son have a normal life?
- How serious are the conditions?
- What should I watch for in a baby suspected of having the YY syndrome?
- How much should we accept or discourage his aggressive physical activity?
- What kind of problems might be associated with his excessive height?
- What will he need to understand when he wants to start a family?

testing blood samples for the presence of the YY chromosome.

The main test for recognizing chromosomal disorders is the fluorescence in-situ hybridization (FISH). This method of analyzing the structures of human genetics relies on fluorescent probes designed to link to specific genetic particles such as proteins, genes, or chromosomal material. If the correlating probe cannot link to the material for which it is designed, then the result is accepted as an absence of the material. In testing for YY syndrome, the probes specific to the Y chromosome would be injected into genetic material from the affected person. If examination of the probes detects two Y chromosomes, then the test confirms the person has the YY syndrome.

Treatment and management

There is no treatment to cure the YY syndrome. Because of the mildness of the condition, even treatment specific to the symptoms may not be necessary. The most immediate treatment for the boy with YY syndrome may be speech therapy to address the language delay. However, some of the affected boys have been shown to overcome the language problem eventually, without therapy. The boy may need special services in the school years to alleviate the learning disorder. Again, this may not be necessary. In one study, almost all boys who were identified early with YY syndrome responded well to preschool as their only treatment for learning disability.

It is important for parents and teachers to be understanding and supportive of the YY syndrome boy. Clear limits should be set regarding the aggression; however, those limits should be made in consideration of the boy's need for physical activity. The boy should be encouraged to take part in organized sports.

Prognosis

There is no evidence of lower life expectancies for the YY male. There are no increased threats; particularly, there is no increased susceptibility to disease. As noted above, many YY males go through life not even realizing their condition. As an adult, the YY male can expect to father children; the population tends to be within normal expectancies of fertility.

Zebrafish studies

Definition

Zebrafish studies are research papers and clinical reports based on genetic experiments with zebrafish (*Danio rerio*) in order to better understand and treat human diseases and disorders. Zebrafish are considered to be model animals for this purpose because they share 70% of their genome with humans and 82% of the genes known to cause disease in humans. In addition, because zebrafish are vertebrates, they have the same major organs as humans; they have eyes and mouths, brains, bones and spinal cords, intestines, livers, bile ducts, kidneys, hearts, ears, noses, muscles, blood, and teeth.

Description

Zebrafish biology

Zebrafish are freshwater fishes belonging to the minnow or carp family (Cyprinidae) that are native to southern Asia. They were given their scientific name (*Danio rerio*) in 1822 by Francis Buchanan-Hamilton, a Scottish physician and zoologist who lived in India for many years. Zebrafish are plentiful in the wild; they live in slow-flowing shallow streams or stagnant fresh water in rice paddies or ponds. They can tolerate water as cold as 12.3 °C (54.1 °F) or as warm as 38.6 °C (101.5 °F). Because of their hardiness and adaptability, zebrafish are considered a species of least concern for risk of extinction by the International Union for Conservation of Nature (IUCN).

Zebrafish are small animals, averaging 1.8–3.7 cm (0.7–1.5 in) in length in the wild, although they can grow as long as 5 cm (2 in) in laboratory settings. Their name comes from the five uniform horizontal blue stripes on the side of the body. Male zebrafish have gold stripes between the blue ones and are shaped somewhat like a torpedo; females have silver stripes instead of gold and have larger bellies than the males. Zebrafish live about a

year in the wild, two to three years in captivity, and up to five years in a laboratory or specialized aquarium.

Zebrafish have a generation time of three months, which means that they can produce four consecutive generations of fish within a year. They reproduce by spawning, in which the adults release eggs and sperm into the water, which is where fertilization occurs. There must be a male zebrafish present for the female to ovulate (produce eggs). Unlike most fish species, zebrafish spawn around daybreak, which makes it easier for researchers to collect the embryos. Female zebrafish can lay a clutch of hundreds of eggs every two or three days. When fertilization occurs, the eggs become transparent, which is one reason why zebrafish are popular with researchers. The embryos develop very rapidly, compared to most mammals; after three hours, the embryo already contains

Colored scanning electron micrograph (SEM) of newly hatched zebrafish. These fish are used to study embryonic development. The eyes (red) can be seen in the heads. Zebrafish eggs develop rapidly (2-4 days), are transparent, and they develop outside the mother's body, allowing observation of the differentiation of the cells into different body organs. Zebrafish live in fresh water and are found in India. (Steve Gschmeissner/Science Source)

thousands of cells. The fish's head and tail begin to form 16 hours after fertilization, and the tail separates from the body by 24 hours. The zebrafish is sexually mature at three months of age.

History of zebrafish research

Zebrafish were brought to Europe and North America along with other subtropical fish species in the 1850s, when families as well as scientists began to keep small freshwater fish in aquariums as pets as well as for study. In the United States, zebrafish were accidentally released into the wild in Connecticut, New Mexico, Florida, and California. As the fish multiplied in their new habitats, they became popular with aquarium hobbyists, particularly with inexperienced fish keepers. Zebrafish were and still are inexpensive additions to a home aquarium; as of 2021 they cost between \$1.89 and \$2.10 each in most American pet stores.

Scientific research using zebrafish began with George Streisinger (1927–1984), a molecular biologist at the University of Oregon who became interested in the fish after purchasing some from a local pet store in Eugene. Streisinger was the first scientist to clone a vertebrate, and the zebrafish was the vertebrate he chose to clone; he described his procedure in a 1981 article published in *Nature*. Much of Streisinger's research into genetic engineering in zebrafish was not published until after his death. His last paper, on the use of ultraviolet light to induce mutations in zebrafish, appeared in *Genetical Research* in 1992. Streisinger was, however, almost singlehandedly responsible for the explosion of interest in zebrafish as model animals in the 1980s and following. Many well-known researchers in the field studied under him at the University of Oregon; subsequently, the number of journal articles on zebrafish listed by the National Library of Medicine rose from four per year in 1980 to 48 in 1990; 657 in 2000; 1,895 in 2010; and 4,383 in 2020. A peer-reviewed journal titled *Zebrafish* began publication in 2004 and is still actively seeking contributors as of 2021.

In addition to Streisinger's leadership, it was the technological changes in the fields of gene editing and next-generation sequencing that led to the establishment and funding of the zebrafish laboratories and research cores spread across the United States. The Zebrafish Information Network (ZFIN) was started after a meeting at Cold Spring Harbor in 1994 to establish an online database of information about zebrafish as a model organism. Scientists at the National Human Genome Research Institute (NHGRI) successfully created transgenic zebrafish using genetically modified sperm in 2004. The Zebrafish Core at NHGRI was started in 2006, as was the Zebrafish International Resource Center (ZIRC) at the University of

Oregon. Sequencing of the zebrafish genome began in 2001; the complete genome was published in 2013. There are about 1.5 billion base pairs in the zebrafish genome, spread over 25 chromosomes. By contrast, the human genome contains over three billion base pairs.

In 2015, researchers at NHGRI developed transgenic zebrafish that can be used as animal models of melanoma, leukemia, and pancreatic cancer. In 2014, the NIH began to fund the Undiagnosed Diseases Network (UDN), a consortium of clinical sites, a central biorepository, and animal research centers. One of the network's two Model Organism Screening Centers (MOSCs) is located at the University of Oregon and focuses on zebrafish research. In 2016, ZFIN joined together with five other model organism databases to form the Alliance of Genome Resources.

Purpose

As of 2021, zebrafish are most intensively researched as model organisms for gaining a better understanding of a wide range of disorders in humans and some possible pharmacological treatments for those disorders. The small size of these fish, their speed of reproduction, the high numbers and transparency of their embryos, and their preference for living in groups (shoaling) make it much easier and less expensive to store zebrafish in a laboratory than an equivalent number of mice. In addition, zebrafish eggs are fertilized outside the female's body, which makes their embryos much easier to manipulate genetically than mouse embryos. Zebrafish eggs can be fertilized in vitro (in a laboratory container), and the fertilized eggs can be injected with DNA or RNA to permanently alter their genetic makeup. The genetically engineered embryos can then be allowed to mature, reproduce, and generate a new line of zebrafish.

As of 2021, the most recent technology used to edit the zebrafish genome is CRISPR/Cas9, a molecular technique that involves the introduction of Cas9, a nuclease (specialized enzyme) attached to a synthetic guide RNA (gRNA) into a cell in a living organism. The Cas9 can be directed to cut the genome at a specific spot and remove, add, or replace the DNA at the location of the cut. The CRISPR/Cas9 technique was introduced in 2009; it is less expensive, more accurate, and easier to use than older genome editing methods. It can also target several genes at the same time. Most zebrafish researchers now use CRISPR/Cas9.

The zebrafish genome can be edited to produce transgenic zebrafish, whose DNA has been altered by the introduction of DNA from another species, including human DNA. Transgenic zebrafish can be used to model certain human diseases. Genome editing can also be used

KEY TERMS

Animal disease model—A living nonhuman animal used during the research and investigation of human disease. The animal model may or may not be genetically engineered.

Base pair (bp)—Any of the complementary nucleotide bases (adenine-thymine and cytosine-guanine in DNA; adenine-uracil and cytosine-guanine in RNA) held together by weak hydrogen bonds. Base pairs form links between the two strands of DNA.

Clustered regularly interspersed short palindromic repeats (CRISPR)—A technique for genome editing that involves creating a short RNA sequence called guide RNA (gRNA) that matches a targeted sequence of DNA in the organism's genome. The gRNA guides an enzyme called Cas9 to the target DNA sequence. The enzyme cuts the genome at this location, and the researcher can either remove DNA, add new DNA, or modify the DNA.

Clutch—The name for a group of eggs laid by zebrafish, other fish, amphibians, or birds.

Generation time—The average length of time elapsed between two consecutive generations in an animal population. The generation time for zebrafish is about three months.

Genome—The total amount of genetic information within an organism's chromosomes, including its genes and DNA sequences.

Genome editing—A type of genetic engineering in which DNA can be inserted, changed, deleted, or replaced within the genome of a living organism.

Knock-in—Referring to an organism that has been genetically engineered to alter a specific genetic locus by a one-for-one substitution of DNA sequence information or by the addition of DNA sequence information that is not found on the genetic locus in question.

Knockout—Referring to an organism that has been genetically engineered to lack one or more specific genes.

Mendelian disease—A disease caused by a single mutated gene; also called a single-gene disease.

Model organism—A nonhuman species (which may be a plant, animal, or bacterium) that is studied to

yield understanding of particular biological events or processes in the expectation that discoveries made in the model organism can be applied to other species.

Monogenic disease—Another term for a single-gene disorder.

Next-generation sequencing—A general term for massively parallel sequencing of large portions of DNA base pairs, performed by first fragmenting the DNA, reading the individual fragments in parallel, and then reassembling the reads to obtain the sequence of the entire genome.

Nuclease—A type of enzyme responsible for breaking the chemical bonds between the subunits (nucleotides) that make up DNA and RNA. A specific nuclease called Cas9 is used in CRISPR genome editing technology.

Oncogene—A gene that has the potential to cause cancer.

Phenotype—The set of externally observable characteristics or traits of an organism.

Poikilotherm—A term applied to any animal that cannot regulate its core body temperature and has a body temperature that varies with its surroundings. The opposite is a homeotherm, which refers to an organism (including humans) that can maintain a warm and fairly constant body temperature independent of the surrounding temperature.

Spawning—The process of releasing both eggs and sperm into water by fish and other aquatic animals.

Transgenic—Referring to an organism in which one or more sequences of DNA from another species have been introduced by artificial means. Animals are typically made transgenic by having a small segment of the other species' DNA injected into an egg or developing embryo.

Vertebrate—Any animal with a segmented spinal column and a distinct head. Vertebrates include fishes, amphibians, reptiles, birds, and mammals.

Wild type (WT)—The typical phenotype of a species as it exists in nature, without any genome editing.

to produce so-called knockout zebrafish, in which one or more specific genes have been removed from the genome. This is done in the zebrafish to determine whether loss of that gene's function causes the same

symptoms as those observed in the human patient. The opposite is knock-in genome editing, in which additional DNA sequences are inserted into the genome. Knock-in engineering is more complicated than its knockout

counterpart, but it is thought to be more promising in using zebrafish to understand human disorders.

Known disorders

There are a number of known human diseases and disorders affecting the organs and body systems that humans share with zebrafish that are under investigation:

- **Cancer.** Since 2011, mutated zebrafish have been used to study leukemia, melanoma, liver cancer, and pancreatic cancer. Zebrafish with mutated forms of the *BRAF* and *NRAS* oncogenes will develop melanoma. Zebrafish have also been used to study cancer predisposition genes (CPGs), which are genes whose mutations increase an individual's risk of developing cancer in later life. Mutated zebrafish have been used to study the genes associated with Li-Fraumeni syndrome, familial adenomatous polyposis, Peutz-Jeghers syndrome, and Cowden syndrome.
- **Developmental disorders.** Zebrafish can be used to study the role of genes in the development of the brain and nervous system. For example, researchers have discovered the gene (*ZC4H2*) responsible for an X-linked disorder known as Miles-Carpenter syndrome by working with zebrafish models. Knockout zebrafish lacking the *PHF21A* gene have been used to study Potocki-Shaffer syndrome, a microdeletion syndrome characterized by intellectual disability, defects in the bones that form the skull, vision disorders, and abnormal facial features.
- **Mental disorders.** Zebrafish subjected to inbreeding, coupled with environmental stress, develop a form of depression comparable to human depression. Inbred male zebrafish have fewer offspring, and the embryos have a high mortality rate.
- **Disorders of blood formation (hematopoiesis) and the circulatory system.** The transparency of zebrafish embryos allows researchers to observe the formation of blood cells and their circulation in the fish's body. In addition, the discovery that zebrafish can regenerate heart muscle tissue after injury offers promise for developing treatments for human heart disease.
- **Eye disorders.** Researchers at the National Eye Institute (NEI) are studying support cells in the zebrafish's eye that start multiplying in response to damage to the retina, the light-sensitive tissue at the back of the eye. A detailed understanding of this repair process may offer clues to repairing retinal damage in the human eye.
- **Immune system disorders.** The close similarities between the zebrafish and human immune systems, as well as the transparency of zebrafish embryos, assist researchers in imaging the interactions that occur between zebrafish bodies and a wide range of viruses, bacteria, and parasites. One specific disease that has been extensively studied in

QUESTIONS TO ASK YOUR DOCTOR

- What is your opinion of zebrafish studies? Do you think they will continue to contribute to scientific understanding of human disorders?
- Which human disease or body system do you think is best suited to zebrafish studies?
- Do you think that zebrafish will be useful in identifying diseases that are currently undiagnosed?

zebrafish is tuberculosis; another is influenza. Zebrafish can be used to analyze the effectiveness of various anti-infective drugs as well as the effectiveness of the innate immune system in fending off infections.

- **Musculoskeletal disorders.** Zebrafish are frequently used to study muscular dystrophies, a group of disorders characterized by muscle wasting, abnormal contractions of the muscles, and general weakness. Because zebrafish embryos readily absorb chemicals, they are a model organism for analyzing the effectiveness of possible drug therapies for the muscular dystrophies.

Unknown diseases

In addition to their versatility in studying known genetic syndromes, infectious diseases, and developmental disorders, zebrafish are being used to identify genes responsible for rare disorders. Of the 20,000 genes in the human genome, only about 4,000 have been linked to monogenic (single-gene or Mendelian) disorders or rare diseases. It is estimated that there may be as many as 6,000 additional genes remaining to be identified for Mendelian disorders and rare diseases. While a specific rare disease may affect only a few hundred people in the general American population, there are at least 25 million Americans coping with these diseases as of 2021, according to the CDC.

As noted above, the NIH established and began to fund the Undiagnosed Diseases Network (UDN) in 2014. The network includes two Model Organism Screening Centers or MOSCs, one of which contains a zebrafish core. The zebrafish core identified 16 candidate genes for unknown diseases during Phase I of the NIH funding. To date, almost 5,000 Americans with rare disorders have applied to be study participants, and 470 have received diagnoses of their diseases.

The Zebrafish International Research Center (ZIRC) at the University of Oregon makes mutant and transgenic strains of zebrafish available to qualified scientists in

other institutions. These fish are much more expensive than their pet shop counterparts; ZIRC currently charges \$20 for a pair of wild-type zebrafish, and \$200 for a pair of mutant or transgenic zebrafish. Mutant or transgenic embryos cost \$125 for a set of 100. These are the prices charged to academic institutions; the prices are doubled for commercial buyers.

Limitations

In spite of the widespread use of zebrafish as model animals, there are limitations on the research that can be done with them. To begin with, about 18% of the genes known to cause diseases in humans do not exist in zebrafish. Another limitation is that zebrafish cannot be used to model tissues or body parts in humans that zebrafish lack, such as external genitalia, mammary glands, lungs, and the prostate gland. In regard to mental and behavioral disorders, the human brain is far more complex than the zebrafish's brain.

Still another limitation of zebrafish as model animals is that they are not mammals; they are poikilotherms, which means that they must adapt to a wider variety of external temperatures, because they cannot regulate their internal body temperatures as mammals do. This factor means that zebrafish metabolize drugs at a different rate and possibly in a different manner than mammals do, which complicates evaluating the findings of drug studies in zebrafish. In humans, the presence of a placenta moderates the effects of drugs on a human fetus before birth, whereas zebrafish embryos absorb drugs directly from the surrounding water without any modification by the mother's metabolism.

Clinical trials

There are seven clinical trials that involve the use of zebrafish registered with the NIH as of mid-2021. One study is based on the findings of zebrafish studies of trifluoperazine as a possible treatment for a rare genetic blood disorder called Diamond Blackfan anemia or DBA. Another study used zebrafish to study the ability of human leukemia cells to survive in zebrafish embryos and evaluate the effectiveness of newer anticancer drugs. A third clinical trial being conducted in Italy will use zebrafish embryos transplanted with cancer cells from patients with liver, pancreatic, stomach, colorectal, esophageal, and gall bladder cancer to predict the chemotherapy regimen best suited to each patient.

Zellweger spectrum

Definition

Zellweger spectrum is a group of inherited disorders characterized by the reduction or absence of structures within the cell called peroxisomes, and by the accumulation of various unmetabolized substances in the blood and bodily tissues. Peroxisomes are a type of organelle or structure within the cell. They produce more than 80 different enzymes that are essential for cells to break down waste and remove it from the cell. When there are too few peroxisomes in a cell, waste products and other toxins build up and eventually kill the cell. When enough cells die, the tissue in which they live dies.

The disorder arises in infancy and results in visual and hearing impairments, decreased muscle tone, poor growth, intellectual disability, decreased coordination, liver damage, and abnormal development of facial

Sixteen-month-old Adrian Alfaro (left) looks up at his father, Jose. Adrian has Zellweger syndrome, a disease that stunts muscle development and takes away mobility. (Modesto Bee/Getty Images)

structures. There is no cure for the disorder, and treatment is limited to the relief of symptoms.

Description

Living bodies are made of millions of individual cells specifically adapted to carry out particular functions. Within cells are even smaller structures, called organelles, which perform different jobs and enable the cell to serve its ultimate purpose. One type of organelle is the peroxisome, whose function is to break down waste materials or to process materials that, if allowed to accumulate, would prove toxic to the cells.

Peroxisomes break down various materials through the use of enzymes (proteins that assist in biochemical reactions), and 80 different peroxisomal enzymes have been identified. These enzymes are made by the cell and transported into the peroxisome by a complex process, requiring at least 15 other proteins. In some cases, an absence or deficiency of these proteins results in a failure to transport enzymes into peroxisomes, leaving the cell unable to metabolize various substances. These substances build up in the blood stream and deposit in various tissues, causing damage.

Zellweger spectrum results from an abnormality in the transport of enzymes into the peroxisome, manifesting as absent or reduced functioning peroxisomes. As a consequence of peroxisome deficiency, various substances accumulate in the bloodstream, including phytanic acid, pipecolic acid, hydroxycholestanic acids, glyoxylate, and substances called very-long-chain fatty acids (VLCFA). Mutations in at least two different genes that encode proteins that participate in the transport of enzymes to the peroxisome have been identified in Zellweger spectrum.

Zellweger spectrum disorder is a group of conditions that affect many parts of the body and have similar signs and symptoms. The Zellweger spectrum includes Zellweger syndrome, neonatal adrenoleukodystrophy (NALD), and infantile Refsum disease (IRD). These conditions were once thought to be distinct disorders but are now considered to be part of the same condition spectrum. Zellweger syndrome is the most severe form of the Zellweger spectrum disorder, NALD is intermediate in severity, and IRD is the least severe form.

The most severe form of Zellweger spectrum is Zellweger syndrome. Signs and symptoms of the condition develop during the newborn period and include weak muscle tone (hypotonia), feeding problems, hearing and vision impairment, and seizures. These problems are caused when a substance called myelin, the protective covering of nerves that promotes transmission of nerve impulses, is broken down. Destruction of myelin (demyelination) leads to loss of white matter, the part of the brain that contains the most myelin. Other symptoms of Zellweger syndrome include lethal problems in the liver, heart, and kidneys, and skeletal abnormalities, including a large space between the bones of the skull (fontanel) and characteristic bone spots known as chondrodysplasia punctata that can be seen on x-ray. Affected individuals have distinctive facial features, including a flattened face, broad nasal bridge, and high forehead. Children with Zellweger syndrome typically do not survive beyond the first year of life.

Neonatal adrenoleukodystrophy (NALD) is a moderate form of Zellweger spectrum. Individuals with this disorder have abnormalities of the adrenal glands, the white matter of the brain, and the testes. Symptoms of this disorder include seizures, hyperactivity, strabismus (crossed eyes), paralysis, hearing loss, and muscular weakness.

IRD is the least severe of the Zellweger spectrum disorders. The disorder arises in infancy and results in visual and hearing impairments, decreased muscle tone, poor growth, intellectual disability, decreased coordination, liver damage, and abnormal development of facial structures. There is no cure for the disorder, and treatment is limited to the relief of symptoms.

Genetic profile

Zellweger spectrum is a genetic condition and is inherited or passed on in a family. The genetic abnormality for the disorder is inherited as an autosomal recessive trait, meaning that two mutant genes are needed to display the disease. A person who carries one mutant gene does not display the disease and is called a carrier. A carrier has a 50% chance of transmitting the gene to their

children. A child must inherit the same abnormal gene from each parent to display the disease.

There are at least 12 known genetic mutations that cause the Zellweger spectrum disorders. These mutations alter production of a protein called peroxin that is essential to the production of peroxisomes, the organelles responsible for removing waste and toxins from the cell. When peroxisomes are not produced normally, the symptoms of Zellweger spectrum arise.

Mutations in the *PEX1* gene are responsible for most cases of Zellweger spectrum and are found in 70% of people who have this disorder.

Demographics

The combined incidence of all Zellweger spectrum disorders is estimated to be approximately 1 in 50,000. It is unclear whether these disorders are distributed equally among different geographical areas and ethnic groups.

Signs and symptoms

Symptoms associated with Zellweger spectrum arise at birth or very early infancy and affect many different organ systems and tissues, resulting in severe disease. Babies with Zellweger spectrum show decreased muscle tone and a failure to grow at appropriate rates. Characteristic facial features are often present, including prominent forehead and folds at the inner aspect of the eye, flat face and bridge of the nose, and low-set ears. While affected children are able to walk, the gait may be irregular due to abnormalities in muscle coordination.

High levels of unmetabolized substances can deposit in the fatty sheaths surrounding nerves, causing damage and resulting in peripheral neuropathy. "Peripheral neuropathy" is the term for dysfunction of the nerves outside of the spinal cord, causing loss of sensation, muscle weakness, pain, and loss of reflexes. Nerves leading to the ears can be affected, resulting in hearing loss or deafness. IRD also results in cerebellar ataxia, an abnormality in a specific part of the brain (the cerebellum), resulting in loss of coordination and unsteadiness. People with Zellweger syndrome have extensive impairments in cognitive function resulting in severe intellectual disability.

Zellweger spectrum often affects the eyes, causing retinitis pigmentosa, a degeneration of the retina resulting in poor nighttime vision, followed by loss of peripheral vision and eventually loss of central vision late in the course of the disease. Nystagmus (uncontrollable movements of the eye) may also be present due to related nervous system damage. Other manifestations of Zellweger spectrum include enlargement of the liver, poor digestion,

and abnormally low blood cholesterol. Early osteoporosis (decalcifications of the bone) may also develop, leading to bone fractures or compression of the spinal bones.

Diagnosis

Zellweger spectrum is diagnosed through a combination of consistent medical history, physical exam findings, and laboratory and genetic testing. Typically, parents bring newborns to their physicians because of the signs of low muscle tone. Other times, the characteristic facial abnormalities or a failure to grow at appropriate rates is noted. These findings raise suspicion for a genetic syndrome or metabolic disorder, and further tests are conducted.

Laboratory tests reveal several abnormalities. Blood samples from patients with Zellweger spectrum show accumulation of various substances including phytanic acid, pipecolic acid, hydroxycholestanic acids, glyoxylate, and VLCFA. Other measurements demonstrate low levels of plasmalogen, a substance normally produced by action of the peroxisomal enzymes. Immunoblot tests that measure levels of specific proteins will show deficiencies in many peroxisomal enzymes. Additional studies will reveal abnormal electrical responses from the retina and various nerve groups.

Finally, genetic testing can be performed. When a diagnosis of Zellweger spectrum is made in a child, genetic testing of the *PEX1* gene can be offered to determine if a specific gene change can be identified. If a specific change is identified, carrier testing can be offered to relatives. In families where the parents have been identified to be carriers of the abnormal gene, diagnosis of Zellweger spectrum before birth is possible. Prenatal diagnosis is performed on cells obtained by amniocentesis (withdrawal of the fluid surrounding a fetus in the womb using a needle) at about 16–18 weeks of pregnancy or by chorionic villus sampling (CVS) where cells are obtained from the chorionic villi (a part of the placenta) at 10–12 weeks of pregnancy.

Treatment and management

There is no cure or standard course of treatment for Zellweger spectrum. Currently, treatment of patients has generally involved only supportive care and symptomatic therapy. Several studies suggest that a diet that is free of phytanic acid can limit symptoms of Zellweger spectrum. A useful adjunct to dietary treatment is plasmapheresis. Plasmapheresis is a procedure by which determined amounts of plasma (the fluid component of blood that contains the unmetabolized substances) is removed from the blood and replaced with fluids or plasma that are free of accumulated substances. While treatment strategies

KEY TERMS

Autosomal recessive—A pattern of genetic inheritance where two abnormal genes are needed to display the trait or disease.

Carrier—A person who possesses a gene for an abnormal trait without showing signs of the disorder. The person may pass the abnormal gene on to offspring.

Cerebellar ataxia—Unsteadiness and lack of coordination caused by a progressive degeneration of the part of the brain known as the cerebellum.

Enzyme—A protein that catalyzes a biochemical reaction or change without changing its own structure or function.

Mutant—A change in the genetic material that may alter a trait or characteristic of an individual or manifest as disease.

Organelle—Small, sub-cellular structures that carry out different functions necessary for cellular survival and proper cellular functioning.

Peripheral neuropathy—Any disease of the nerves outside of the spinal cord, usually resulting in weakness and/or numbness.

Peroxisome—A cellular organelle containing different enzymes responsible for the breakdown of waste or other products.

Retinitis pigmentosa—Progressive deterioration of the retina, often leading to vision loss and blindness.

may mitigate some of the symptoms experienced by the patient with Zellweger spectrum, they do not slow the progression of the disorder.

Experimental studies are underway to investigate whether several different agents can be of additional use. Patients with Zellweger spectrum have reduced levels of docosahexaenoic acid and arachidonic acid that can be corrected with the administration of oral supplements. There are some reports of improvement in symptoms with these therapies, and trials to formally investigate these claims are now in progress. Other scientific laboratories are investigating the usefulness of agents that stabilize peroxisomes in the treatment of Zellweger spectrum, but the experiments are still in their early stages.

Patients with Zellweger spectrum should be seen regularly by a multidisciplinary team of health care providers, including a pediatrician, neurologist, ophthalmologist, cardiologist, medical geneticist specializing in metabolic disease, nutritionist, and physical/occupational therapist. Genetic

QUESTIONS TO ASK YOUR DOCTOR

- What are the most common symptoms of Zellweger spectrum?
- What changes in the body are responsible for these symptoms?
- What treatments are recommended for this disorder?
- Are there organizations that provide support and information for families with a child affected by Zellweger spectrum?

counseling can help people with Zellweger spectrum, those who are carriers of the abnormal gene, or those who have a relative with the disorder, learn more about the disease, inheritance, testing, and options available to them so they can make informed decisions appropriate to their families.

Prognosis

For patients with Zellweger spectrum, some success has been achieved with multidisciplinary early intervention, including physical and occupational therapy, hearing aids, alternative communication, nutrition, and support for the parents. Although most patients with Zellweger syndrome continue to function in the profoundly or severely intellectually disabled range, some make significant gains in self-help skills, and a small percentage may reach stable condition in their teens. Despite these few successes, the prognosis for individuals with Zellweger spectrum and NALD is poor, with death generally occurring by six months of age. For individuals with IRD, death generally occurs before the second decade of life.

Zimmermann-Laband syndrome

Definition

Zimmermann-Laband syndrome (ZLS) is a rare genetic disorder characterized by dysmorphic abnormalities of the face and oral cavity, and malformations of the hands and feet. It is named for the German anatomist Karl Wilhelm Zimmermann (1861–1935), who identified the first two cases in 1928, and P. F. Laband, an American dentist and oral surgeon who published a case series in 1964. Alternate names for the disorder include Laband syndrome; gingival fibromatosis with abnormal fingers, nails, nose, and ears, and splenomegaly; and gingival fibromatosis, hepatosplenomegaly, and other anomalies.

Description

At the time of birth, infants with ZLS have abnormally long phalanges (the bones in the fingers and toes), and deformed or absent fingernails and toenails (anonychia). Other signs and symptoms of the disorder do not appear until later childhood, particularly gingival fibromatosis. This is a condition in which the gums become unusually large and overgrown, often preventing the eruption of the permanent teeth. Some children with ZLS will also start to show signs of intellectual disability.

Other changes that take place as the child matures into puberty include abnormal flexibility (hyperextension) in the joints of the fingers and toes; coarsening of the facial features, especially the ears and nose; hypertrichosis (excessive amounts of body hair); abnormalities of the skeleton and spine; and hepatomegaly (enlargement of the liver) or splenomegaly (enlargement of the spleen).

Genetic profile

The genetic profile of ZLS has been a subject of controversy since the early 2000s both in terms of the causative

KEY TERMS

Anonychia—The absence of fingernails and toenails.

Dysmorphic—Referring to a malformed or misshapen body part.

Genetic heterogeneity—The production of apparently identical genetic disorders by different genetic mechanisms or by different genes at different positions on the chromosomes.

Gingival—Pertaining to the gums. Gingival fibromatosis refers to an overgrowth of the tissue of the gums.

Hepatomegaly—Enlargement of the liver.

Hyperextension—The movement or extension of joints, bones, or muscles beyond the normal range of motion.

Hypertrichosis—An abnormal amount of hair growth over the body. It may be generalized over the entire body or localized to certain areas of the body.

Macrotia—Abnormally large ears.

Malocclusion—Misalignment or incorrect relation between the teeth in the upper and lower jaws as the jaws close.

Organelle—A specialized subunit within a cell.

Phalanges (singular, phalanx)—The bones that make up the fingers of the hand and the toes of the foot. There are 56 phalanges in the human body.

Philtrum—The vertical groove in the center of the upper lip.

Scoliosis—Abnormal curvature of the spine, usually defined as greater than 10 degrees to the right or left as the doctor faces the patient.

Splenomegaly—Enlargement of the spleen.

Xerostomia—The medical term for dry mouth. It is most often a side effect of medications but is also found in some genetic syndromes.

gene and its pattern of inheritance. In 2003, a team of Bulgarian researchers suggested that the gene that causes ZLS is located on either chromosome 3 or chromosome 8. In 2007, a group of researchers in Boston identified a position for the ZLS gene on the short arm of chromosome 3 at 3p14.3, but did not name a specific candidate gene.

Most recently, an international group of researchers based in Europe and Australia reported that mutations

in two genes, *KCNH1* and *ATP6V1B2*, are responsible for Zimmermann-Laband syndrome. *KCNH1* is located on the long arm of chromosome 1 at 1q32.2. The *KCNH1* gene has been linked to Temple-Baraitser syndrome, another rare genetic disorder characterized by absent or malformed nails, intellectual disability, and various deformities of the facial features. Mutations in this gene accounted for a large proportion of the cases of ZLS that the researchers studied. The *ATP6V1B2* gene codes for a protein that governs the acidity of the organelles within cells. It has been linked to several syndromes characterized by deafness, malformations of the skeleton, and intellectual disability. The *ATP6V1B2* gene is located on the short arm of chromosome 8 at 8p21.3. Mutations in this gene were responsible for two cases of ZLS. The researchers concluded that ZLS is a genetically heterogeneous disorder; that is, a single genetic disorder that can be caused by different genetic mechanisms or by different genes at different locations on the chromosomes.

Genetic heterogeneity also accounts for disagreements among geneticists as to the inheritance pattern of ZLS. While some maintain that ZLS is inherited in an autosomal dominant pattern, others have reported cases of ZLS that indicate an autosomal recessive pattern of inheritance. It is possible that the genetic mutations identified as causing ZLS as of 2015 follow different inheritance patterns, but further research is needed to confirm this possibility.

Demographics

ZLS is a very rare disorder, with only 44 cases worldwide reported between 1928 and 2011. An additional four cases were identified between 2011 and 2015. The syndrome affects males and females in equal numbers.

It was thought at first that ZLS was largely limited to people of East Indian origin living in either India or the Caribbean, but additional cases have been reported in families of European and Japanese origin. Although the disorder is very rare, it seems likely that all racial and ethnic groups are affected.

Signs and symptoms

The signs and symptoms of Zimmermann-Laband syndrome vary somewhat in severity from patient to patient; in addition, some patients diagnosed with the syndrome have additional physical abnormalities.

The signs and symptoms typical of ZLS are as follows:

- **Mouth and gums:** Gingival fibromatosis severe enough to interfere with chewing as well as the eruption of the child's permanent teeth; recurrent gum infections;

QUESTIONS TO ASK YOUR DOCTOR

- Does my child have ZLS?
- If so, on what do you base the diagnosis?
- Should we consider genetic testing to confirm the diagnosis?
- Will my child require special education as well as specialized dental treatment?
- How can I help my child cope with the social complications caused by his or her unusual facial features?

failure of teeth to close properly (malocclusion); drooling; speech problems; sores at the corner of the mouth; premature loss of teeth; and dry mouth (xerostomia). In some cases the gums may become overgrown to the point of covering the teeth completely and protruding from the child's mouth.

- **Facial features:** Abnormally narrow face; unusually large and soft ears (macrotia) with long earlobes; large lips and unusually wide mouth; enlarged nose with a bulbous tip; abnormally large philtrum (the groove in the middle of the upper lip).
- **Skin:** Hypertrichosis, which may appear over most of the body or only on limited areas of skin. The body hair in patients with ZLS is typically long, soft, and downy.
- **Hands and feet:** Abnormally long phalanges in the fingers and toes, with large swellings at the tips of the fingers and toes. The joints are often unusually flexible (hyperextensive), and the nails are either malformed or absent.
- **Spine and skeleton:** Scoliosis (sideways curvature of the spine) occurs in about half of patients with ZLS. Other abnormalities include misshapen vertebrae, abnormally shaped ribs, and poor muscle tone.
- **Nervous system:** About half of children with ZLS display moderate to severe intellectual disability. The disorder also carries an increased risk of epilepsy in later childhood.
- **Internal organs:** About half of patients with ZLS have an enlarged spleen (splenomegaly) and enlarged liver (hepatomegaly).

Other symptoms that have been reported in some patients with ZLS include:

- Vision disorders, including extreme nearsightedness, cataracts, and cross eyes (strabismus).

- Abnormalities in the structure of the heart, including unusually thick walls in the lower chambers of the heart (ventricular hypertrophy); dilated cardiomyopathy, a condition in which the heart becomes enlarged and cannot pump blood efficiently; and an abnormally dilated aortic arch.
- Kidney stones.
- Hearing loss.
- In males, an unusually long penis.

Diagnosis

As of 2015, the diagnosis of ZLS was based on observation of the infant's hands and feet at birth, and on the identification of gingival fibromatosis, characteristic facial features, hypertrichosis, intellectual disability, and skeletal abnormalities as the child grows older. Molecular genetic testing has become available only recently due to delayed discovery of the genes responsible for the syndrome. As of mid-2015, there was one laboratory in Quebec offering sequence analysis of the entire coding region of the *ATP6V1B2* gene; there were no laboratories offering tests of the *KCNH1* gene.

Treatment and management

There is no cure for Zimmermann-Laband syndrome, but early diagnosis and treatment are critical to lower the risk of later complications. Treatment is symptomatic. Gingival fibromatosis usually requires specialized treatment by a team of pediatric dentists, oral surgeons, and orthodontists to prevent the development of malocclusion, speech difficulties, drooling, and premature loss of teeth associated with gum overgrowth. In some cases the excess gum tissue may require repeated surgeries, as the symptom returns in about 20% of cases. Speech therapy is often needed if the fibromatosis has not been corrected at an early stage.

Hypertrichosis associated with ZLS and other genetic syndromes cannot be cured but must be treated by various cosmetic methods of hair removal. These may include shaving, waxing, electrolysis, laser hair removal, and chemical depilatories.

Children diagnosed with ZLS should be followed from early childhood for signs of intellectual disability, and monitored for indications of seizure activity. Those with scoliosis and other abnormalities of the spine and joints should receive physical therapy and may require referral to an orthopedic surgeon to correct severe deformities. Most children will need some type of psychotherapy or counseling in order to cope with the unusual appearance of their hands, feet, and facial features.

Prognosis

Zimmermann-Laband syndrome is not a life-threatening disorder. As far as is known, patients diagnosed with ZLS can expect normal lifespans. Patients do, however, vary in the severity of their facial dysmorphism, their mental capacity, their spinal and skeletal abnormalities, and their hypertrichosis; those with milder symptoms generally have fewer problems with social and educational adjustment.

Rebecca J. Frey, PhD

Zinner syndrome

Definition

Zinner syndrome is a congenital syndrome in males classified by the presence of a cyst in the seminal vesicle with an ipsilateral (on the same side as the cyst) renal agenesis (kidney not forming correctly in utero) and ejaculatory duct obstruction. The association between seminal vesicle cyst and ipsilateral renal agenesis was identified in 1914. The later finding of the affiliated ejaculatory duct obstruction completed the triad of Zinner syndrome.

Description

The development of the kidney begins in the growing fetus roughly between 4 and 7 weeks, starting with a mesonephric duct. Embryologically speaking, the mesonephric duct gives rise to the uterine bud. This uterine bud develops toward the center of the metanephric bud to ultimately form the kidney. When this does not occur properly in the developing fetus, it is possible for the kidney and/or the ejaculatory ducts to form incorrectly, leading to a malformed kidney and a buildup of fluid, known as a cyst, in the seminal vesicle. These are the two common coinciding features of Zinner syndrome, where ipsilateral agenesis is present in roughly 70%–80% of patients and infertility is present in 37% of cases.

If there is a diagnosis of seminal vesicle cyst with ipsilateral renal agenesis, the syndrome is classified as a structural congenital anomaly. In the case of Zinner syndrome, the signs and symptoms of renal agenesis do not often present, since the normal kidney can carry out the functions necessary for the entire body. Seminal vesicle obstruction and ejaculatory duct blockage will present itself when a male becomes sexually active, depending on the size of the cyst. A link between the kidney and the male reproductive system is evident in the embryology of the mesonephric duct, which develops into parts of the bladder, urethra, seminal vesicle, vas deferens, and epididymis, among others. If the developing or embryologically changing mesonephric duct is compromised early in the pregnancy, a change in the ultimate structure and function of one or more reproductive and/or excretory parts will likely result. For example, if the distal portion of the duct is not developed correctly, the ejaculatory duct and seminal vesicle will be affected in such a way that fluid blockage will lead to cyst formation. This improper development of the distal portion of the mesonephric duct will also result in abnormal budding of the ureter, ultimately causing agenesis of the kidney itself. Also, depending on the size of the cysts formed early in development and/or the region of malformation

KEY TERMS

Agenesis—Lack or failure of development.

Congenital—Existing since birth.

Cyst—A closed sac having a distinct membrane and developing abnormally in a cavity or structure of the body.

Embryology—The study of the growing embryo.

Epididymis—A system of ducts emerging posteriorly from the testes that holds sperm during maturation and that forms a tangled mass before uniting into a single coiled duct that is continuous with the vas deferens.

Ipsilateral—Situated or appearing on or affecting the same side of the body.

Laparoscopic—Visual examination of the abdomen by means of a laparoscope.

Mesonephric duct—A duct that in the male gives rise to the reproductive system.

Metanephric bud—An embryological precursor to renal organs.

Renal—As related to the kidney.

Seminal vesicle—Either of a pair of glandular pouches that lie on either side of the male reproductive tract and in human males secrete a sugar- and protein-containing fluid into the ejaculatory duct.

Stenosis—A narrowing or constriction of the diameter of a bodily passage or orifice.

of the duct, infertility may result. A variation of the changes in these structures is determined by the structure or timing of the malformation.

Genetic profile

Much like other congenital anomalies, the genetic link to Zinner syndrome is currently unknown. At some point during the development of the embryo a malformation may occur, leading to a congenital anomaly. Some anomalies are often symptom free and are incidental findings during examination. Other congenital anomalies that affect major organs or organ systems oftentimes present themselves with signs and symptoms during early development, although sometimes they present later in life.

Congenital anomalies are fairly common within the population today. The World Health Organization (WHO) reports that approximately half of all known congenital anomalies cannot be linked to a specific cause

such as a specific gene mutation (missense, frameshift, point, etc.). The WHO does, however, state that socioeconomic or demographic factors may be an influence in the incidence of congenital anomalies. These include, but are not limited to, countries and areas with low income and lower access to nutrition and medical support during pregnancy. Age of pregnancy is also a contributing factor to many congenital birth defects.

Demographics

As of 2015, only about 100 cases of Zinner syndrome had been recorded. It is possible that the asymptomatic nature of the syndrome is the reason behind the low numbers of recorded cases to date. Due to the anatomical orientation of the anomaly, only males are affected.

Signs and symptoms

Although oftentimes asymptomatic, Zinner syndrome may present itself with pain in the lower abdominal region and pain in the perineal region, both made worse with ejaculation; a disruption in the flow of urine; pain while urinating; blood in the urine; blood in the semen; and infertility.

Infertility is reportedly common in 37% of cases of Zinner syndrome. The presentation of symptoms is highly associated with the size and exact location of the cysts inside the seminal vesicle, as a cyst of less than 5 cm is oftentimes asymptomatic and is an incidental finding of a routine prostate exam. Cysts between 5 cm and 12 cm are referred to as moderate, and cysts 12 cm and larger are often referred to as severe, as they can cause urinary or stool blockage. Inflammation of the anatomy surrounding the cyst (including, but not limited to, the ipsilateral epididymis and prostate) may also be involved, presenting with a deep, dull, diffuse ache in the lower abdomen. Due to the anatomy affected by the anomaly, signs and symptoms do not typically show until a male is sexually active, as pain during ejaculation is a major finding.

Diagnosis

Upon initial examination of a male suspected to have Zinner syndrome, a digital rectal examination will show a large, soft mass posterior to the prostate indicative of a cyst in the region of the seminal vesicle. If a mass is palpated, many tests are then utilized for diagnosing Zinner syndrome while ruling out other pelvic, renal, prostate, or reproductive syndromes. Further abdominopelvic palpation and observation will reveal normal-sized testes and no kidney findings with normal neurological evaluation. Urinalysis may show blood in the urine otherwise

QUESTIONS TO ASK YOUR DOCTOR

- Will I always have pain during intercourse? If so, how can this be treated?
- What is the best way to check for infertility?
- What are my options for reproduction if I am indeed infertile?
- What is the state of my kidney, and do I have proper kidney function? If my kidney function is altered, what can I do for treatment?
- Are there support groups for coping with infertility?
- How often should I be examined for progression of my disorder?
- How large is my cyst, and what is my best treatment option?

within normal limits. Blood tests are typically within normal limits as well, although, depending on the blockage, inflammatory markers such as ESR/SED rate may be increased. Sperm count will likely be low.

The diagnosis of Zinner syndrome is often concluded via diagnostic imaging. A CT will show a high intensity zone of a mass with easily distinguishable borders of water or near-water attenuation located slightly superior to the prostate gland. An MRI exam will be able to identify if ipsilateral renal agenesis is present with or without stenosis of the vas deferens, and is also necessary for differentiating seminal vesicle cysts from other pelvic cysts, such as cysts in the prostate gland or Müllerian ducts. Other methods of diagnostic testing include intravenous urography or rectal ultrasonography. An ultrasound will reveal a pelvic mass with a thick and irregular wall that does not echo.

Due to the nature of the disorder, diagnosis is often made between the ages of 20–50 years, when males are more sexually active and/or trying to reproduce.

Treatment and management

Conservative treatment of a mild to moderately symptomatic Zinner syndrome may be appropriate and successful. This may include a short-term course of oral antibiotics and a 6-month course of alpha-blockers for decreasing pain, inflammation, and prostate-related symptoms. Fine needle aspiration may also be an option for conservative removal of the cyst without major surgery.

Treatment of a seminal vesicle cyst that is moderately to severely symptomatic includes robotic laparoscopic removal of the cyst itself. Recent studies have shown this to be the method of choice in the removal of a cyst, as the recovery time is low and the prognosis is good.

Management of Zinner syndrome should include routine observations for prevention of life-threatening diagnoses associated with this disorder including squamous cell carcinoma of the seminal vesicle with which the cyst is associated.

Prognosis

The prognosis for Zinner syndrome is very good. As of 2015, there had only been one case noted in the literature where Zinner syndrome progressed into cancer. With proper treatment and management of the condition, patients should expect to live a full life.

Zygote

Definition

The zygote is the single cell that is formed when the sperm cell fertilizes the egg cell. The zygote divides multiple times, producing identical copies of itself. The cells produced by the division of the zygote form the developing embryo, fetus, and baby. The zygote is the first step in the formation of a new person.

Illustration of a human zygote. (Sebastian Kaulitzkil/Shutterstock)

Description

When the sperm fuses with the egg, a cascade of events begins. Additional sperm are prevented from fertilizing the egg. The membranes of the egg and sperm combine, producing one single cell. The egg and sperm prepare to fuse their genetic material (DNA/chromosomes). Finally, the genetic material combines to produce the zygote with one complete set of chromosomes.

Most cells in the human body have two pairs of 23 chromosomes; that is, 46 chromosomes total. One set of 23 chromosomes is inherited from the mother, and the complementary set is inherited from the father. When the egg and sperm are formed, the two sets of chromosomes divide evenly, from 46 to 23 chromosomes to produce eggs and sperm with 23 chromosomes each. This ensures that when the egg and sperm fuse during conception, the original number of chromosomes (46) is restored.

The reduction of each parent cell from 46 to 23 chromosomes ensures that each parent contributes half of his or her genetic material to form the zygote and the offspring shares 50% of his or her genes with each parent. Duplication of the single zygote occurs through a complete division of the single ball of cells. This begins the process of forming the fetus and eventually the baby. The first division produces two identical cells, the second produces four cells, the third produces eight cells, etc. After many cell divisions, the cells begin to specialize and differentiate (form particular tissues and organs).

Fertilization usually occurs in the fallopian tube, and the first few cell divisions occur as the developing embryo moves to the uterus. The first division occurs about 30 hours after fertilization. As the zygote divides, some of the cells formed will develop into the placenta. Approximately six days after fertilization, the ball of cells attaches to the uterine wall.

Sex determination

Men and women each have 22 pairs of non-sex chromosomes and two sex chromosomes. Men's sex chromosomes are X and Y. A mature sperm cell that has undergone the chromosome division process from 46 to 23 chromosomes produces a cell that is either X or Y. Women's sex chromosomes are X and X. The eggs that women produce have only X chromosomes. Therefore, the sperm determines whether the zygote is XY or XX, which is the initial step on the biological path to becoming a male or female.

Developmental periods

The term “embryo” refers to the developing baby between the second week after conception and the eighth week after conception. Doctors use the term “fetus” from the ninth week after conception to birth. A pregnancy is broken down into three trimesters. The first trimester begins with the first day of the woman's last menstrual period and each trimester is three calendar months.

Twins

Twins may arise in two ways. Identical twins are called “monozygotic” because both individuals are formed from the same zygote. As the zygote divides to form the baby, two separate individuals form instead of one. Fraternal twins are called “dizygotic” because each individual develops from a different zygote. Two eggs are ovulated, and a separate sperm fertilizes each egg. Therefore, identical twins have exactly the same DNA in each cell and fraternal twins share the same amount of DNA as brothers and sisters. Sometimes it is impossible to tell monozygotic twins from dizygotic twins based on the placenta and the fetal membranes. If a person wants to determine whether twins are monozygotic or dizygotic, DNA studies of blood cells will provide a definitive answer.

Abnormalities

The zygote normally contains two complete sets of 23 chromosomes, and two copies of every gene. If the egg or sperm that fuse to form the zygote is abnormal, the zygote will also be abnormal. For example, Down syndrome is caused by an extra chromosome number 21

from the egg or sperm cell. Since the cells formed by division of the zygote are identical to the zygote, any abnormality in the zygote will be in every cell of the baby.

Abnormalities can also arise when the zygote begins to divide. This type of abnormality is usually severe, eventually leading to a miscarriage. If an abnormality occurs after the zygote has divided one or more times, the baby will have some normal cells and some abnormal cells. This situation is referred to as “mosaicism” and may be used to describe the person’s condition.

Molar pregnancies

Molar pregnancies can occur in one of two ways. Sometimes the original cell that duplicates and divides to form the fetus is completely of paternal origin. The chromosomes in a sperm duplicate themselves, then proceed to divide as if they were a normal zygote. These pregnancies are completely abnormal and miscarry. Another type of molar pregnancy occurs when two sperm fertilize one egg. The zygote is triploidy and has 69 chromosomes instead of 46. Although some fetal parts can be seen, these pregnancies normally miscarry in the first or second trimester.

Birth defects

The term “birth defect” describes many different types of abnormalities, including physical malformations. Abnormalities of anatomical structures may be significant or insignificant; minor variations in structure are common. Approximately 3% of newborns have major malformations. The causes are: chromosome abnormalities (6%–7%), inherited genetic conditions (7%–8%), environmental factors (7%–10%), and multifactorial causes (20%–25%). The cause of the remaining 50%–60% of malformations is unknown. Multifactorial refers to causes with both genetic and environmental components. Environmental factors include exposures to drugs, chemicals, or other substances that affect the development of the fetus while he/she is in the uterus. Substances that cause birth defects are referred to as teratogens.

Artificial reproductive technology

Couples may pursue assisted reproductive technologies for a number of reasons. If a couple has artificial insemination, the sperm is inserted into the uterus when the woman is ovulating. Fertilization then occurs as it would normally. If a couple has in vitro fertilization (IVF), the egg and sperm are mixed outside the body in the laboratory. The zygote forms in a petri dish if fertilization occurs. After a number of cell divisions, the developing embryo is placed in the woman’s uterus. If the

KEY TERMS

Chromosome—A microscopic thread-like structure found within each cell of the body and consisting of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Changes in either the total number of chromosomes or their shape and size (structure) may lead to physical or mental abnormalities.

Gene—A building block of inheritance, which contains the instructions for the production of a particular protein, and is made up of a molecular sequence found on a section of DNA. Each gene is found on a precise location on a chromosome.

Teratogen—Any drug, chemical, maternal disease, or exposure that can cause physical or functional defects in an exposed embryo or fetus.

sperm are incapable of fusing with the egg themselves, the sperm may be injected into the egg. This additional step to the IVF procedure is called intracytoplasmic sperm injection (ICSI).

Preimplantation diagnosis is possible for a number of genetic diseases. Couples may pursue this if they are at a significant risk for having a child with a disease that could be diagnosed prior to becoming pregnant through preimplantation diagnosis. The procedure is like that of in vitro fertilization, with an additional step. After fertilization occurs and the zygote has begun to divide, a single cell is removed. Removing the cell does not harm the other cells. The cell that is removed is tested for the genetic disease for which the couple is at risk. Multiple developing embryos are tested. Only the embryos that do not have the condition are placed in the woman’s uterus to complete development.

The development of a person from the zygote is a fascinating and amazing process. It is a difficult area to study because scientists cannot manipulate human embryos to observe the effects, and the development of the fetus cannot be directly observed. Researchers still have many unanswered questions. Following a doctor’s recommendations from prior to the pregnancy throughout pregnancy (such as folic acid intake and avoidance of alcohol and other drugs) increases the chances that the development of a zygote into a full-term infant will be normal. However, there are many babies born with severe birth defects or genetic diseases despite the parents’ efforts at doing everything in their power to prevent a problem. Most birth defects and genetic disorders occur because of an event out of the control of the parents.

CHROMOSOME MAP

A chromosome map indicates the relative positions of the genes that code for certain characteristics. The basic format for writing a gene position is the chromosome number, arm, band, sub-band, and sub-sub-band, if known. An example is 3p22.5.

The chromosome number refers to one of the 22 autosomal chromosomes (numbered 1–22) or one of the two sex-determining chromosomes, X and Y. In the example, the gene is on chromosome 3.

Each chromosome has two arms, which are separated by a centromere, the pinched-in area at or above the middle of the chromosome. The short arm, labeled p, is above the centromere, and the long arm, q, is below it. In the case of the example gene, it is found on the short arm (p) of chromosome 3, or 3p.

The arms are further divided into cytogenetic bands (regions) numbered 1, 2, 3, etc. The numbers start at the

centromere and increase toward the end of the arm, known as the telomere. These bands can only be seen when stained and viewed under a microscope. Sub-bands, which are numbered the same way as bands, may be visible within bands at greater magnifications. Therefore, the exact location of the example gene is the short arm (p) of chromosome 3, band 2, sub-band region 2, and a sub-sub band 5.

The following 24 illustrations demonstrate the approximate gene location for several of the genes relating to disorders mentioned in this encyclopedia. Disorders known to be related to a specific chromosome but not necessarily at an exact location have been placed below the chromosome. These chromosome maps are in no way complete; rather, they provide an introduction to understanding relative size differences of human chromosomes and where geneticists have located the genes associated with the source of certain genetic disorders.

GLOSSARY

The glossary is an alphabetical compilation of terms and definitions listed in the **Key Terms** sections of the main body entries. Although the list is comprehensive, it is by no means exhaustive.

A

AADC INHIBITORS. Drugs that block the amino acid decarboxylase, one type of enzyme that breaks down dopamine. Also called DC inhibitors, they include carbidopa and benserazide.

ABDOMINAL HERNIA. Bulging of an organ or tissue through the muscle of the stomach wall.

ABDUCENS NERVE. Cranial nerve VI; the nerve that extends from the midbrain to the lateral rectus muscle of the eye and controls movement of the eye toward the ear (abduction).

ABDUCTION. Turning away from the body.

ABLATION. A general term for medical techniques for destroying a cancer (or other unwanted tissue) without removing it.

ABSCCESS. A localized collection of pus or infection that is walled off from the rest of the body.

ABSENCE SEIZURE. A type of epileptic seizure characterized by a brief loss of, and return to, consciousness, usually without being followed by a period of confusion or disorientation.

ACANTHOCYTOSIS. The presence of acanthocytes in the blood. Acanthocytes are red blood cells that have the appearance of thorns on their outer surface.

ACANTHOSIS NIGRICANS. A brownish-black hyperpigmentation of the skin, most often found in the folds of the body. It can be caused by genetic disorders as well as by certain malignancies and endocrine disorders.

ACCIDENTAL INCEST. Sexual activity or marriage between persons who are unaware of a close familial relationship between them.

ACCOMMODATION. The ability of the lens to change its focus from distant to near objects. It is achieved through the action of the ciliary muscles that change the shape of the lens.

ACETYLCHOLINESTERASE (ACHE). An enzyme found in nerve tissue.

ACHONDROGENESIS. A genetic disorder of skeletal development with three subtypes, one of which (achondrogenesis type II) is caused by mutations in the same gene as hypochondrogenesis.

ACHONDROPLASIA. An autosomal dominant form of dwarfism caused by a defect in the formation of cartilage at the ends of long bones. Affected individuals typically have short limbs, a large head with a prominent forehead and flattened profile, and a normal-sized trunk.

ACHROMATOPSIA. The inability to distinguish any colors.

ACID MALTASE. The enzyme that regulates the amount of glycogen stored in muscle cells. When too much glycogen is present, acid maltase is released to break it down into waste products.

ACIDOSIS. A condition of decreased alkalinity resulting from abnormally high acid levels (low pH) in the blood and tissues. Usually indicated by sickly sweet breath, headaches, nausea, vomiting, and visual impairments.

ACQUIRED ANGIONEUROTIC EDEMA. Abbreviated AANE, or AAE, this is a nonhereditary form of angio edema that generally begins to show symptoms in, or after, the fourth decade of life.

ACQUIRED IMMUNITY. Also called specific immunity, refers to immune reaction mediated by B-cells and/or T-cells. Includes humoral and cellular immunity.

ACROCENTRIC. A centromere positioned at the top end of a chromosome.

ACROCEPHALOPOLYSYNDACTYLY SYNDROMES. A collection of genetic disorders characterized by a cone-shaped abnormality of the skull and partial fusing of adjacent fingers or toes.

ACROCEPHALY. An abnormal cone shape of the head.

ACROMELIC. The anatomical term used to denote the end of a limb (arm or leg). In the context of Robinow syndrome, it refers to bones of the hands and feet.

ACROOSTEOLYSIS. Loss of bone tissue at the ends of the fingers and/or toes.

ACROPARESTHESIA. Painful burning sensation in hands and feet.

ACROSOME. The cap at the top of the sperm head that releases egg-penetrating enzymes.

ACTA2. The gene that encodes smooth muscle alpha-2 actin; up to 20% of familial thoracic aortic aneurysms and dissections (TAADs) are caused by mutations in the *ACTA2* gene.

ACTIN. A protein that interacts with myosin during the process of muscle contraction.

ACTION POTENTIAL. The wave-like change in the electrical properties of a cell membrane, resulting from the difference in electrical charge between the inside and outside of the membrane.

ACTIVITIES OF DAILY LIVING (ADL). The skills and practices necessary for functioning in daily life and for participating in one's environment; progressively lost with Alzheimer's disease.

ACUPUNCTURE. An alternative health procedure based on ancient Chinese methods, involving insertion of thin needles at specific pressure points in the body.

ACUTE MYELOGENOUS LEUKEMIA (AML). A life-threatening disorder of the bone marrow in which a large number of abnormal white blood cells accumulates in the marrow and reduces the production of normal red and white blood cells and platelets. It is also called acute myeloid leukemia.

ACUTE PHASE REACTANTS. Blood proteins whose concentrations increase or decrease in reaction to the inflammation process.

ACUTE STRESS DISORDER (ASD). An anxiety disorder similar to PTSD but with symptoms occurring immediately after a traumatic event and resolving within a month.

ADDUCTED THUMBS. Thumbs clasped across the palm.

ADDUCTION. Movement toward the body. In Duane retraction syndrome, turning the eye inward toward the nose.

ADENOCARCINOMA. A general term for a type of cancer that originates in glandular tissue or behaves like glandular tissue. About 10% to 15% of cancers of the cervix are adenocarcinomas.

ADENOMA. A benign tumor that develops in glandular tissue. A thyroid adenoma may produce large amounts of thyroid hormone that disrupt the normal thyroid feedback system.

ADENOMATOUS. Derived from glandular structures.

ADENOMATOUS POLYPS (ADENOMAS). A growth in the colon that may become cancerous if not removed.

ADENOSINE DEAMINASE 2 (ADA2). The enzyme produced by the *CECR1* gene and required for blood-vessel and immune-system development and maintenance; *CECR1* gene mutations that result in little or no ADA2 can cause recurrent fevers and strokes in children and other syndromes in children and adults.

ADENOSINE TRIPHOSPHATE (ATP). An organic molecule found in all living organisms, involved in energy production for metabolic processes and RNA synthesis.

ADJUVANT THERAPY. Treatment given to patients who are at risk of having microscopic untreated disease present but have no obvious symptoms.

ADRENAL CRISIS. A life-threatening complication of salt-losing (salt-wasting) congenital adrenal hyperplasia with 21-hydroxylase deficiency.

ADRENAL GLAND. A triangle-shaped endocrine gland, located above each kidney, that synthesizes aldosterone, cortisol, and testosterone from cholesterol. The adrenal glands are responsible for salt and water levels in the body, as well as for protein, fat, and carbohydrate metabolism.

ADRENAL INSUFFICIENCY. Problems with the adrenal glands that can be life threatening if not treated. Symptoms include sluggishness, weakness, weight loss, vomiting, darkening of the skin and mental changes.

ADRENOCORTICOTROPIC HORMONE (ACTH). A pituitary hormone that acts on cells of the adrenal cortex to produce male sex hormones and hormones that control water and mineral balance in the body.

ADVANCED BONE AGE. The bones, on x-ray, appear to be those of an older individual.

ADYSPLASIA. A term referring to the combination of renal agenesis (complete absence of one or both kidneys) and renal dysplasia (developmental anomaly of the kidney).

AFFECTIVE FLATTENING. A loss or lack of emotional expressiveness; sometimes called blunted or restricted affect.

AFFORDABLE CARE ACT (ACA). The Patient Protection and Affordable Care Act ("Obamacare"); signed into law by President Barack Obama in March of 2010, the ACA overhauled the U.S. healthcare system.

AFLATOXIN. A mycotoxin, produced by several species of *Aspergillus* fungi, that is a known carcinogen.

AGANGLIONOSIS. Section of bowel in which the normal enteric nerves are absent.

AGE-ASSOCIATED MEMORY IMPAIRMENT (AAMI). A condition in which an older person suffers some memory loss and takes longer to learn new information; AAMI is distinguished from dementia in that it is not progressive and does not represent a serious decline from the person's previous level of functioning.

AGENESIS. Failure of an organ, tissue, or cell to develop or grow.

AGENESIS OF THE CORPUS CALLOSUM. An absence of the structure in the brain that connects the two hemispheres of the brain.

AGENESIS/HYPOPLASIA OF THE CORPUS CALLOSUM. Birth defect in which the two halves of the brain are not properly separated.

AGNOSIA. Loss of the ability to recognize objects by use of the physical senses.

AGONIST. A chemical or biological agent that binds to a receptor and activates the receptor to produce a biological response.

AGYRIA. The absence of gyri, or convolutions, in the cerebral cortex.

AKATHISIA. Agitated or restless movement, usually affecting the legs and accompanied by a sense of discomfort; a common side effect of neuroleptic medications.

AKINESIA. A loss of the ability to move; freezing in place.

AKINETIC MUTISM. A medical condition in which the patient is unable to move (akinetik) or speak (mutism).

ALBUMINURIA. Abnormally high levels of albumin (the most abundant protein in blood) in the urine. Albuminuria may be visible as white foam in the urine.

ALDOSTERONE. A steroid hormone produced by the adrenal gland that regulates salt and fluid balance in the body and is deficient in congenital adrenal hyperplasia.

ALGORITHM. A set of rules for solving a problem in a finite number of steps.

ALKALINE. Having a basic pH; not acidic.

ALKALINE PHOSPHATASE (ALP). An enzyme that is found in the blood and that helps to break down proteins in the body. ALP can be present in different forms depending on where it was synthesized. ALP can be made in the liver, kidneys, intestines, and bones.

ALKALINIZATION. The process of making a solution more basic, rather than more acidic, by raising the pH.

ALLELE. Any of the alternative versions of a gene that are present in the population.

ALLELIC. Related to the same gene.

ALLELIC VARIANTS. A disease is said to have allelic variants when different mutations in the same allele result in identical, or nearly identical, symptoms. An allele is the combined locations of a gene on the two paired chromosomes that contain this gene.

ALLERGEN. A substance or organism foreign to the body; allergens stimulate the immune system to produce antibodies.

ALLERGY. A condition in which the immune system is hypersensitive to contact with allergens; an abnormal response by the immune system to contact with an allergen; a condition in which contact with an allergen produces symptoms such as inflammation of tissues and production of excess mucus in the respiratory system.

ALOPECIA. Loss of hair or baldness.

ALOPECIA AREATA. A nonscarring hair loss syndrome characterized by smooth, round, or oval hairless areas on the scalp.

ALPHA-FETOPROTEIN (AFP). A chemical substance produced by the fetus and found in the fetal circulation. AFP is also found in abnormally high concentrations in most patients with primary liver cancer.

ALPHA-SYNUCLEIN. A protein that forms aggregates in nerve cells in certain types of dementia.

ALPHA THALASSEMIA. A genetic disorder in which mutations in the *HBA1* and *HBA2* genes on chromosome 16 lead to impaired production of a subtype of hemoglobin known as alpha globin. The severity of the disorder depends on how many of the four alpha globin chains are affected by mutations.

ALTERATION. Change or mutation in a gene, specifically in the DNA that codes for the gene.

ALTERNATE COMPLEMENT PATHWAY. A cascade of enzymatic reactions that produce antibacterial proteins. This pathway helps to ward off infections.

ALX. Genes encoding transcription factors that are required for normal prenatal development of the head and face; mutations in the *ALX1* gene cause frontonasal dysplasia (FND) type 3; mutations in *ALX3* cause FND1; mutations in *ALX4* cause FND2.

ALZHEIMER'S DISEASE (AD). A progressive neurodegenerative disease characterized by loss of function and

death of nerve cells in several areas of the brain, leading to mental deterioration; the most common cause of dementia.

AMASTIA. A birth defect involving the absence of mammary glands.

AMBIGUOUS. Unclear or open to more than one interpretation.

AMELOGENESIS IMPERFECTA. A hereditary dental defect characterized by discoloration of the teeth.

AMENORRHEA. Absence of menstruation, usually defined as missing one or more menstrual periods.

AMINO ACIDS. Organic compounds that form the building blocks of protein. There are 20 types of amino acids (8 are “essential amino acids” that the body cannot make that and must be obtained from food).

AMINOSALICYLATES. Anti-inflammatory medications containing 5-aminosalicylic acid (5-ASA) that are commonly used to treat colitis.

AMNESTIC MILD COGNITIVE IMPAIRMENT (AMCI). An early symptom of Alzheimer’s disease in which there is mild impairment but normal cognitive functioning is still present.

AMNIOCENTESIS. A procedure performed at 16 to 18 weeks of pregnancy in which a needle is inserted through a woman’s abdomen into her uterus to draw out a small sample of the amniotic fluid from around the baby. Either the fluid itself or cells from it can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

AMNION. The thin, protective sac that suspends the fetus in a protective amniotic fluid.

AMNIOTIC FLUID. Fluid contained in a sac within the uterus that surrounds and protects the fetus during its development.

AMNIOTIC SAC. Contains the fetus, which is surrounded by amniotic fluid.

AMNIOTIC SAMPLE. Sample of amniotic fluid, the protective fluid surrounding a fetus in the womb.

AMPLIFICATION. A process by which something is made larger. In clotting, only a very few chemicals are released by the initial injury; they result in a cascade of chemical reactions that produces increasingly larger quantities of different chemicals, resulting in an appropriately sized, strong fibrin clot.

AMYGDALA. Any of the four basal ganglia in each cerebral hemisphere that are involved in triggering fear.

AMYLASE. A digestive enzyme found in saliva or pancreatic fluid that breaks down starch and sugars.

AMYLOID. Any of a group of insoluble abnormal proteins that accumulate in body organs and tissues and interfere with their normal functioning.

AMYLOID PRECURSOR PROTEIN (APP). A protein that forms beta-amyloid in the brain when it is not correctly broken down; mutations in the APP gene can cause early-onset familial Alzheimer’s disease.

AMYLOIDOSIS. Accumulation of amyloid deposits in various organs and tissues in the body such that normal functioning of an organ is compromised.

AMYOPLASIA. The most common form of arthrogryposis multiplex congenita, characterized by sporadic and recurrent contractures of the wrists, elbows, and knees; an abnormal internal rotation of the shoulders; and clubfeet.

AMYOTROPHY. Wasting of the muscles.

ANABOLISM. The energy-using process of building up complex chemical compounds from simpler ones in the body.

ANAGEN. The growth phase of the human hair growth cycle.

ANALOGUE. A drug or other chemical compound that resembles another in structure or constituents but has different effects.

ANALYTE. A chemical compound that is the subject of a laboratory test.

ANAPLASTIC. Undifferentiated, appearing to have an immature cell type.

ANDROGEN INSENSITIVITY SYNDROME. An intersex condition found in people who are chromosomally male (karyotype XY) but have a mutation in the *AR* gene that makes them unable to respond to male sex hormones. As a result, they may have some or all of the physical traits of a female.

ANDROGENS. Steroid hormones that contribute to the development of male sex organs and male secondary sexual characteristics.

ANEMIA. A blood condition in which the level of hemoglobin or the number of red blood cells falls below normal values. Common symptoms include paleness, fatigue, and shortness of breath.

ANENCEPHALY. The absence of a major portion of the brain, upper skull, and scalp during fetal development.

ANESTHESIA. Lack of normal sensation (especially to pain) brought on by medications just prior to surgery or other medical procedures.

ANESTHESIA OF THE SKIN. A loss of feeling or sensation in the skin associated with spine-related injury or disorders.

ANESTHETIC. A drug used to temporarily cause loss of sensation in an area of the body. An anesthetic may either be general, associated with a loss of consciousness, or local, affecting one area only without loss of consciousness. Anesthetics are administered via either inhalation or needle injection.

ANEUPLOIDY. A condition in which an abnormal number of chromosomes exists in the nucleus of a cell. Trisomy 18 and trisomy 13 are examples of aneuploid conditions.

ANEURYSM. An abnormal blood-filled bulge in a blood vessel, and especially an artery, resulting from weakening (as from disease) of the vessel wall.

ANGELMAN SYNDROME (AS). A disorder caused by the deletion or absence of active imprinted genes.

ANGINA. A sensation of chest pain, squeezing, or pressure, usually arising from reduced blood supply to the heart muscle due to obstruction or spasm of the coronary arteries.

ANGIOGENESIS. The medical term for the formation of new blood vessels out of preexisting blood vessels.

ANGIOGRAPHY. A procedure that shows the system of blood vessels and the blood flow in a portion of the body. Requires an injection of dye to help see the vessels.

ANGIOID STREAKS. Gray, orange, or red wavy branching lines in Bruch's membrane.

ANGIOKERATOMA. A skin rash made up of red bumps. The rash most commonly occurs between the navel and the knees.

ANGIOMA. A benign tumor composed of blood vessels or lymph vessels.

ANGIONEUROTIC EDEMA. Recurrent episodes of swelling of the tissues of the body caused by an overactive immune system. This is also called angioedema.

ANGIOTENSINOGEN. A plasma globulin (protein) formed in the liver and directly involved in the regulation of blood pressure.

ANGLE-CLOSURE GLAUCOMA. An increase in the fluid pressure within the eye due to a complete, and sometimes sudden, blockage of the fluid-drainage passages.

ANHEDONIA. The inability to experience satisfaction or pleasure from activities or interests that the person previously enjoyed. It is a common symptom of depression.

ANHIDROSIS. Complete inability to sweat in response to heat.

ANIMAL DISEASE MODEL. A living nonhuman animal used during the research and investigation of human disease. The animal model may or may not be genetically engineered.

ANKYLOSIS. Immobility of a joint due to the formation of new bone at the site of inflammation.

ANOMALOUS. Irregular or different from normal.

ANOMALOUS VENOUS RETURN. Normally, the veins that bring blood containing oxygen from the lungs to the heart (called pulmonary veins) are connected to the left atrium. In this situation, the pulmonary veins are connected to the right atrium.

ANOMALY. A malformation or abnormality in any part of the body.

ANONYCHIA. The absence or abnormal development of the fingernails and toenails.

ANOPHTHALMIA. Congenital absence of the eyes.

ANOSMIA. Impairment or absence of the sense of smell.

ANTERIOR CHAMBER. The fluid-filled front portion of the eye that lies between the iris and the cornea (the transparent front part of the eye that covers the iris and pupil).

ANTERIOR FONTANELLE. The soft spot on the skull of an infant that is located in the center of the head just behind the hairline.

ANTERIOR HORN CELLS. Subset of motor neurons within the spinal cord.

ANTI-ANDROGEN DRUGS. Drugs that block the activity of the male hormone.

ANTIBIOTICS. A group of medications that kill or slow the growth of bacteria.

ANTIBODY. A protein produced by the mature B cells of the immune system that attach to invading microorganisms and target them for destruction by other immune system cells.

ANTICIPATION. A genetic phenomenon in which the symptoms of a disease appear at an earlier age in each successive generation.

ANTICOAGULANT. Drugs used to prevent blood clots.

ANTIDIURETIC HORMONE (VASOPRESSIN). A hormone that acts on the kidneys to regulate water balance.

ANTIGEN. A substance or organism that is foreign to the body and stimulates a response from the immune system.

ANTIGEN PRESENTING CELL. Cells that are able to present foreign antigen in conjunction with MHC proteins to the immune system.

ANTINUCLEAR ANTIBODIES (ANAS). Abnormal antibodies against cell nuclei. They are found in the blood of people with autoimmune diseases such as lupus.

ANTIPSYCHOTICS. Medications for reducing symptoms of a severe mental disorder such as schizophrenia; sometimes used for behavioral ASD symptoms.

ANUS. The opening at the end of the intestine that carries waste out of the body.

AORTA. The main artery located above the heart that pumps oxygenated blood out into the body. Many congenital heart defects affect the aorta.

AORTIC DILATATION. Weakening and stretching of the aorta that can occur with TAAD-associated gene mutations and lead to an aneurysm or aortic dissection.

AORTIC DISSECTION. A splitting of the layers of the aorta wall that causes blood to leak between the layers.

AORTIC ROOT. The location where the aorta (main heart blood vessel) inserts in the heart. Enlargement of the aortic root can cause it to rupture.

AORTIC VALVE. Valve joining the left ventricle to the aorta in the heart.

APERT SYNDROME. A genetic syndrome characterized by syndactyly as well as malformations of the skull and face. It is named for Eugène Apert, the French physician who first described it in 1906.

APHASIA. Impairment of the ability to comprehend or communicate through speech, writing, or signs due to brain dysfunctions.

APLASIA. Defective development resulting in absence of all or part of an organ or tissue.

APLASIA CUTIS CONGENITA (ACC). A group of disorders with different causes and a common characteristic of absence of skin in a defined area.

APLASTIC ANEMIA. A disorder in which the bone marrow and its blood stem cells are damaged such that it cannot produce mature red blood cells, white blood cells, or platelets.

APNEA. An irregular breathing pattern characterized by abnormally long periods of the complete cessation of breathing.

APOENZYME. An enzyme that cannot function without assistance from other molecules called cofactors.

APOLIPOPROTEIN E (APOE). A protein that transports cholesterol and helps remove it from the bloodstream; the gene encoding one form of this protein, APOE-4, is associated with an increased risk of late-onset Alzheimer's disease.

APOPTOSIS. The normally programmed cell death process in which cells die in order to be replaced with new cells.

APPENDECTOMY. The procedure to surgically remove an appendix.

APPENDICITIS. Inflammation of the appendix.

APPENDIX. A portion of intestine attached to the cecum.

APRAXIA. Impairment of the ability to make purposeful movements without paralysis or loss of sensation.

AQUEOUS HUMOR. Fluid produced by the ciliary body and contained within the front chamber of the eye.

ARACHNODACTYLY. A condition characterized by abnormally long and slender fingers and toes.

ARNOLD-CHIARI MALFORMATION. A congenital anomaly in which parts of the brain protrude through the opening in the base of the skull into the spinal column.

ARRHYTHMIA. Abnormal heart rhythm, examples are a slow, fast, or irregular heart rate.

ARTERIAL. Term used to describe an artery or the entire system of arteries.

ARTERIOLE. The smallest type of artery.

ARTERIOPATHY. Damage to blood vessels.

ARTERIOSCLEROSIS. Hardening of the arteries that often results in decreased ability of blood to flow smoothly.

ARTERIOVENOUS MALFORMATION (AVM). Abnormal direct connection between the arteries and veins (blood vessels) that may range in size from very small to large. AVMs may lead to bleeding or aneurysm formation.

ARTERY. A blood vessel that carries blood away from the heart to peripheral tissues.

ARTHRITIS. An inflammation of one or more joints that causes pain, swelling, stiffness, and limited movement.

ARTHROCHALASIA. Excessive looseness of the joints.

ARTHROGRYPOSIS (PLURAL, ARTHROGRYPOSES). A congenital musculoskeletal condition in which the infant has contractures of the joints in two or more areas of the body.

ARTHROPATHY. Any disease or disorder that affects joints.

ARTIFICIAL INTELLIGENCE. Abbreviated as AI, artificial intelligence is the ability of computers or computer-driven devices to make decisions with real-time data based on machine learning.

ASCITES. An abnormal collection of fluid in the abdominal cavity. It is most often caused by cirrhosis, metastatic liver cancer, or other severe liver disease.

ASPERGER SYNDROME. A term previously used to describe mild autism in individuals with normal intelligence and language skills; now classified as an ASD.

ASPHYXIA. Lack of oxygen. In the case of cerebral palsy, lack of oxygen to the brain.

ASPIRATION PNEUMONIA. Lung infection due to food or liquids accidentally getting into lungs.

ASPLENIA. The absence of the spleen or of normal splenic function in the body. It may be either congenital or acquired.

ASSAY. A laboratory test designed to identify and measure the amount of a specific substance.

ASSISTED REPRODUCTIVE TECHNOLOGY (ART). A collective term for a group of procedures done to address problems with fertility. ART includes such techniques as in vitro fertilization, cryopreservation of donated gametes or embryos, and pre-implantation genetic diagnosis.

ASSOCIATION. A non-random occurrence in two or more individuals of the same group of anomalies that are not otherwise known to be a sequence or syndrome.

ASTIGMATISM. A cause of poor eyesight, usually due to a refractive error caused by an irregularly shaped cornea.

ASTROCYTES. Glial cells that occur in the brain and spinal cord.

ASTROCYTOMA. Tumor of the central nervous system derived from astrocytes.

ASYMMETRY. Lack of similar size, length, and shape on both sides of the body.

ASYMPTOMATIC. Without symptoms.

ATAXIA. A deficiency of muscular coordination, especially when voluntary movements are attempted, such as grasping or walking.

ATHEROSCLEROSIS. Thickening and hardening of the inner layer of the arteries due to the accumulation of plaque; a risk factor for Alzheimer's disease.

ATHETOSIS. A condition marked by slow, writhing, involuntary muscle movements.

ATLASTIN-1. A protein encoded by the *ATL1* gene that is important in building and maintaining the structure of the endoplasmic reticulum in the nerve cells of the brain and spinal cord.

ATP. Adenosine triphosphate. The molecule used by the cells of the body for energy.

ATRESIA. An abnormal condition in which a structure that should be hollow is fused shut.

ATRIA. The two chambers at the top of the heart, where blood from the lungs or body pools before entering one of the ventricles. (Singular: atrium.)

ATRIAL FIBRILLATION. An abnormal heart rhythm characterized by the rapid and irregular beating of the two upper chambers (atria) of the heart.

ATRIAL SEPTAL DEFECT (ASD). An abnormal opening between the two upper chambers of the heart (atria).

ATRIOVENTRICULAR COMMUNIS DEFECT. A birth defect of the heart in which the canal between the upper and lower chambers of the heart does not form correctly.

ATROPHIC DERMATOSIS. Wasting away of the skin.

ATROPHIC PHASE. The final phase of LHON where cells in the optic disc and optic nerve have atrophied, resulting in legal blindness. Peripheral vision remains.

ATROPHY. Wasting away of normal tissue or an organ due to degeneration of the cells.

ATTENTION DEFICIT DISORDER (ADD); ATTENTION DEFICIT/HYPERACTIVITY DISORDER (ADHD). Condition characterized by diverse symptoms including age-inappropriate attention span, hyperactivity, and impulsive behavior.

ATYPIA. Any abnormality in a cell.

ATYPICAL PERSONALITY DEVELOPMENT. Another term for pervasive development disorder (PDD-NOS). Other synonyms for this diagnostic category are atypical autism and atypical PDD.

AURA. A disturbance in one or more of the five senses before the beginning of an epileptic seizure.

AURAL ATRESIA. The absence of the external ear canal.

AURICULAR. Pertaining to the ear.

AUTISM SPECTRUM DISORDER (ASD). A general term for a group of neurodevelopmental disorders characterized by difficulties in social interactions, significant abnormalities in speech patterns, and limited but repetitive interests and activities. AUTS2 syndrome is classified as an autism spectrum disorder.

AUTISTIC PSYCHOPATHY. Hans Asperger's original name for Asperger syndrome. It is still used occasionally as a synonym for the disorder.

AUTOANTIBODY. An antibody against the body's own proteins that the immune system produces.

AUTOIMMUNE DISORDERS. Conditions caused by inappropriate immune system activity.

AUTOIMMUNE REACTION. When the body attacks itself, thinking it is being invaded by a foreign body like a bacteria.

AUTONOMIC NERVOUS SYSTEM. The part of the nervous system that regulates heart muscle, smooth muscle, and glands.

AUTOSOMAL. Describes a genetic trait found on a chromosome that is not involved in determining sex.

AUTOSOMAL CHROMOSOMES. Relating to any chromosome besides the X and Y sex chromosomes. Human cells contain 22 pairs of autosomal chromosomes and one pair of sex chromosomes.

AUTOSOMAL DOMINANT. A pattern of genetic inheritance in which only one abnormal gene is needed to display the trait or disorder.

AUTOSOMAL DOMINANT CONDITION. A disease or condition that results from a mutation in only one copy of a gene pair.

AUTOSOMAL DOMINANT MUTATION. An abnormal gene on one of the 22 pairs of non-sex chromosomes that will display the defect when only one copy is inherited.

AUTOSOMAL RECESSIVE. A pattern of genetic inheritance in which two abnormal genes are needed to display the trait or disease.

AUTOSOMAL RECESSIVE CONDITION. A disorder where two copies of a dysfunctional gene must be inherited for the trait to present. The gene is present on the non-sex chromosomes.

AUTOSOMAL RECESSIVE MUTATION. A pattern of genetic inheritance where two abnormal genes are needed to display the trait or disease.

AUTOSOME. Any chromosome that is not a sex chromosome. The human genome has 22 pairs of autosomes.

AXON. Very thin, wire-like extension of nerve cells.

AZOOSPERMIA. The absence of sperm in the seminal fluid.

AZOOSPERMIA FACTOR (AZF). A region of the Y chromosome containing genes that are important for male fertility.

B

B CELLS. Lymphocytes that originate in the bone marrow and make antibodies in response to antigens.

BACTERIOPHAGE. A virus that can destroy a bacterium.

BALANCED CHROMOSOME TRANSLOCATION. A rearrangement of the chromosomes in which two chromosomes have broken and exchanged pieces without the loss of genetic material.

BAND. A specific region of a chromosome that is identified by its characteristic staining pattern and location within a chromosome, as seen in a karyotype. A band is either part of the short arm (p arm) or the long arm (q arm) of a chromosome and is further defined by a numeric location, such as chromosome band 11q24.1.

BANDING. Striped patterns that are visible on stained chromosomes and that are distinctive for each chromosome.

BARDET-BIEDL SYNDROME. A human genetic disorder that affects many body systems. It is characterized principally by obesity, retinitis pigmentosa (a type of progressive retinal dystrophy), polydactyly (having additional fingers or toes), intellectual disability, hypogonadism (a defect of the gonads that results in underproduction of testosterone), and possibly kidney failure.

BIARIUM. A chemical put into a solution and swallowed to help with outlining the gastrointestinal system during an x-ray study.

BIARIUM ENEMA X RAY. A procedure that involves the administration of barium into the intestines by a tube inserted into the rectum. Barium is a chalky substance that enhances the visualization of the gastrointestinal tract on x-ray.

BASAL CELL CARCINOMA. A cancer originating from the skin.

BASAL GANGLIA. An area in the forebrain that contains seven nuclei (clusters of nerve cells) responsible for initiating and controlling voluntary movement along with procedural learning and some habitual actions.

BASE PAIR (BP). Any of the complementary nucleotide bases (adenine-thymine and cytosine-guanine in DNA; adenine-uracil and cytosine-guanine in RNA) held together by weak hydrogen bonds. Base pairs form links between the two strands of DNA.

BASEMENT MEMBRANE. A thin, fibrous, noncellular layer of tissue that anchors and separates the epithelium (the skin and the tissue that lines body cavities) from the underlying connective tissue.

BAYES' THEOREM. A theorem that estimates the probability of an event, based on knowledge of prior conditions that may be related to the event. It is named for Thomas Bayes (c. 1701–1761), an English Presbyterian minister and Fellow of the Royal Society. Bayes' theorem is used in genetic risk assessment for non-Mendelian disorders.

BECKWITH-WIEDEMANN SYNDROME. A collection of health problems present at birth including an omphalocele, large tongue, and large body size.

BENIGN. Referring to a noncancerous tumor that does not spread and is not life-threatening.

BENIGN PROSTATIC HYPERPLASIA (BPH). A noncancerous condition of the prostate that causes growth of the prostate tissue, thus enlarging the prostate and blocking urination.

BENIGN TUMOR. An abnormal proliferation of cells that does not spread to other sites.

BENZOQUINONE ACETIC ACID. Toxic compound that is formed when oxygen reacts with homogentisic acid.

BETA CELLS. The insulin-producing cells of the pancreas.

BETA-2 MICROGLOBULIN. A component protein of class I *MHC*.

BETA-ADRENERGIC BLOCKER. A drug that works by controlling the nerve impulses along specific nerve pathways.

BETA-AMYLOID PLAQUES. Dead or dying nerve cells and cell debris surrounding deposits of beta-amyloid protein in the brain; excess plaques are diagnostic of Alzheimer's disease.

BETA-GALACTOSIDASE. An enzyme that forms a complex with cathepsin A.

BETA-III SPECTRIN. A protein that forms the scaffolding (cytoskeleton) of cell membranes in combination with alpha spectrins.

BIALLELIC. Pertaining to both pair of genes or alleles in a set.

BIFID UVULA. The uvula is the small, teardrop-shaped piece of flesh hanging in the back of the throat; the uvula is bifid if the bottom area is split in two parts.

BILATERAL. Relating to or affecting both sides of the body or both of a pair of organs.

BILATERAL BREAST CANCER. Cancer of both breasts, caused by two separate cancer processes.

BILE. A substance produced by the liver and concentrated and stored in the gallbladder. Bile contains a number of different substances, including bile salts, cholesterol, and bilirubin.

BILE ACIDS. Steroid acids such as cholic acid that occur in bile, an alkaline fluid secreted by the liver and passed into a part of the small intestine where it aids in absorption of fats.

BILE ALCOHOL. A steroid acid with an alcohol group attached.

BILE DUCT. A passageway that carries bile (fluid secreted by the liver involved in fat absorption) from the liver to the gallbladder to the small intestine.

BILIRUBIN. A yellow pigment that is the end result of hemoglobin breakdown. This pigment is metabolized in the liver and excreted from the body through the bile. Bloodstream levels are normally low; however, extensive red blood cell destruction leads to excessive bilirubin formation and jaundice.

BIOBANK. A repository of biological samples (usually human samples) for use in research.

BIOCHEMICAL TESTING. Measuring the amount or activity of a particular enzyme or protein in a sample of blood, urine, or other tissue from the body.

BIOFEEDBACK. A technique in which patients are trained to gain some voluntary control over certain physiological conditions, such as blood pressure and muscle tension, and to promote relaxation.

BIOINFORMATICS. An interdisciplinary scientific field that combines statistics, engineering, mathematics, and computer science to capture and understand biological data.

BIOLOGICS. Substances, usually proteins, that occur naturally in the human body and that are used to treat disease.

BIOMARKER. A distinctive biological indicator of a process, event, disease, or other condition.

BIOPSY. The surgical removal and microscopic examination of living tissue for diagnostic purposes.

BIOPTICS. Glasses that have small telescopes fitted in the lens.

BIOSYNTHESIS. The manufacture of materials in a biological system.

BIOTIN. A growth vitamin of the vitamin B complex found naturally in liver, egg yolks, and yeast.

BIPOLAR DISORDER. Formerly called manic depression, this psychological disorder is characterized by periods of mania followed by periods of depression.

BITEMPORAL CONSTRICTION. Abnormal narrowing of both sides of the forehead.

BLADDER. The organ that stores urine after it flows out of the kidneys and through the ureters.

BLASTOCYST. The phase of human embryonic development that occurs about 5–9 days after fertilization. The blastocyst consists of an outer layer of cells; an inner mass of cells; and a fluid-filled cavity.

BLEPHAROPHIMOSIS. A small eye opening without fusion of the upper eyelid with the lower eyelid at the inner and outer corner of the eye.

BLEPHAROSPASM. An abnormal involuntary twitching or closing of the eyelid. It is the second most common type of focal dystonia.

BLM. The gene that makes a member of a protein family called RecQ helicases.

BLMASH. The mutation in the BLM gene, specifically a 6-bp deletion and 7-bp insertion at nucleotide position 2281 in the BLM cDNA, that causes Bloom syndrome in people of Ashkenazi Jewish ancestry.

BLOOD-BRAIN BARRIER. A mechanism that acts as a sentry for the brain and only allows certain substances in the circulating blood to pass into the brain.

BLOOD SERUM. The clear liquid portion of the blood.

BLOOD VESSELS. A general term for arteries, veins, and capillaries that transport blood throughout the body.

BMPR2. Bone morphogenetic protein receptor 2; it is the gene on which a mutation occurs that is most responsible for cases of familial pulmonary arterial hypertension.

BODY ASYMMETRY. Abnormal development of the body in which the trunk and/or the limbs are not of equal size from one side of the body to the other.

BODY MASS INDEX (BMI). A measure of body fat derived from a person's height and weight. It is calculated by taking the person's weight in kilograms and dividing by the square of the person's height in meters.

BOILS. Painful areas of inflammation.

BONE CYSTS. Fluid- or air-filled space within the bones.

BONE DYSPLASIA. Abnormal bone development.

BONE MARROW. The soft and spongy center of the bones where blood cells are made.

BONE MARROW TRANSPLANT (BMT). A medical procedure used to treat some diseases that arise from defective blood cell formation in the bone marrow. Healthy bone marrow is extracted from a donor to replace the marrow in an ailing individual. Proteins on the surface of bone marrow cells must be identical or very closely matched between a donor and the recipient.

BONE REMODELING. The process of breaking down old bone and building up new bone.

BONE SCLEROSIS. Increased bone density and hardness.

BOOMERANG DYSPLASIA. A lethal genetic syndrome in which fetal bones and cartilage fail to develop normally; the arm and leg bones are bent into the shape of a boomerang. Infants with this disorder die shortly after birth.

BOWMAN'S CAPSULE. A cup-shaped sac that surrounds the glomerulus in the kidney and receives the fluid (filtrate) from the blood filtered by the glomerulus.

BOWMAN'S LAYER. Transparent sheet of tissue directly below the basement membrane.

BRACHYCEPHALY. An abnormal thickening and widening of the skull.

BRACHYDACTYLY. Abnormal shortness of the fingers and toes.

BRACHYMELIA. A general medical term used to describe short limbs.

BRADYCARDIA. An irregularly slow heartbeat.

BRADYKINESIA. Extremely slow movement.

BRAILLE. An alphabet represented by patterns of raised dots that are felt with the fingertips. It is the main method of reading used by the blind.

BRAIN VENTRICLES. A set of four connected cavities that are located deep in the core of the brain. Cerebrospinal fluid (CSF) is made by cells lining the walls of the first two ventricles, then flows through the third, then through the fourth ventricle, before flowing out of the brain. The fluid-filled cavities provide mechanical cushion for the brain, and the CSF provides nutrients to, and carries metabolic wastes away from, the cells of the brain.

BRAINSTEM. The lower part of the brain that connects to the spinal cord.

BRANCHED-CHAIN. An open chain of atoms having one or more side chains.

BRANCHIAL ARCHES. Structures that form during the development of the human embryo as outpouchings of the developing pharynx. The first and second branchial arches in humans give rise to the bony and muscular structures of the face, jaw, and upper neck.

BRANCHING ENZYME. Enzyme responsible for building the branched structure of glycogen stores.

BRANCHIOOTORENAL (BOR) SYNDROME. The second most common autosomal dominant form of syndromic hereditary hearing loss.

BRCA1 AND BRCA2. Breast cancer susceptibility genes; specific inherited mutations in these genes greatly increase the risk of breast and ovarian cancers.

BREAST BIOPSY. A small sample of tissue taken from the breast and studied to diagnose and determine the exact type of breast cancer.

BREAST SELF-EXAM (BSE). Examination by an individual of their own breasts.

BREECH DELIVERY. Birth of an infant feet- or buttocks-first.

BRESLOW DEPTH. A measurement of the thickness of a cutaneous melanoma, used in staging the cancer. It is named for Alexander Breslow, an American pathologist who first identified it as a prognostic factor for melanoma in 1970.

BROAD LIGAMENT. The ligament connecting the ovaries to the uterus.

BRONCHI. Branching tube-like structures that carry air into and out of the lungs. The walls of the bronchi contain circular muscles that can constrict (tighten up to make airways narrower) or dilate (relax to make airways wider). The bronchi divide into smaller bronchioles within the lung tissue.

BRONCHIECTASIS. An abnormal condition of the bronchial tree, characterized by irreversible widening and destruction of the bronchial walls of the lungs.

BRONCHIECTASIS. Permanent enlargement of parts of the airways of the lung.

BRUCH'S MEMBRANE. A membrane in the eye between the choroid membrane and the retina.

BRUTON TYROSINE KINASE (BTK). An enzyme vital for the maturation of B cells.

BUCCAL. Related to the cheek.

BULBAR MUSCLES. Muscles that control chewing, swallowing, and speaking.

BUNDLES OF PROBST. Abnormally developed nerve fibers in the brain.

BUPHTHALMOS. A characteristic enlargement of one or both eyes associated with infantile glaucoma.

C

C1 INHIBITOR. Abbreviated C1-INH, this protein is responsible for preventing the action of the C1 complement molecules in the body. It is this protein that is either deficient or malformed in HANE.

CA-125 (CARBOHYDRATE ANTIGEN 125). A protein that is sometimes high when ovarian cancer is present. A blood sample can determine the level of CA-125 present.

CAESAREAN SECTION. Surgical method to deliver a baby that requires making an incision in the mother's abdomen to remove the infant.

CAFÉ-AU-LAIT SPOTS. Birthmarks that may appear anywhere on the skin; named after the French coffee drink because of the light-brown color of the marks.

CAHUB ACQUISITION OF NORMAL TISSUES. The Cancer Human Biobank, a section of which is dedicated to the storage of tissues for the GTEx project.

CALCIFICATION. The process by which tissue becomes hardened by the depositing of calcium.

CALORIE. A unit of energy that represents the amount of heat a specific amount of food will create in the human body.

CAMPTODACTYLY. A congenital disorder in which one or more fingers are permanently bent. It is a classic sign of FSS as well as of several other genetic syndromes.

CANCER. A disease caused by uncontrolled growth of the body's cells.

CANCER BIOMARKERS. A molecule found in the body like a protein or gene that can suggest prognosis and what type of therapies would be best. In some cases they can even predict the risk of cancer in people who do not have cancer.

CANCER CELLS. These cells have characteristics that distinguish them from normal cells and non-cancerous cells; they are threatening, harmful, and resistant to treatment.

CANCER GENOME ATLAS (CGA). A large multinational initiative for sequencing cancer genomes.

CAPILLARY. A very narrow tube that carries liquid like blood or lymphatic fluid.

CARBOHYDRATE. Any of various natural compounds of carbon, hydrogen, and oxygen (as in sugars and starches) that are burned by the body for energy.

CARCINOGEN. Any substance or radioactive material that is directly implicated in causing cancer.

CARCINOMA. Any cancer that arises in the epithelium, the tissue that lines the external and internal organs of the body.

CARDIAC ARREST. A sudden stop in the circulation of the blood due to the failure of the heart to contract effectively or at all. It is potentially reversible but if untreated can lead to sudden cardiac death.

CARDIAC CONDUCTION DEFECT. An abnormality of the electrical system of the heart that regulates the heartbeat.

CARDIAC MUSCLE. The muscle of the heart.

CARDIAC RHABDOMYOMA. Benign (noncancerous) tumor of the heart muscle.

CARDINAL SYMPTOMS. A group of symptoms that define a disorder or disease.

CARDIOLIPIN. A type of lipid (fatty substance) found almost exclusively in the inner mitochondrial membrane where it is essential for the optimal function of numerous enzymes involved in mitochondrial energy metabolism.

CARDIOMYOCYTES. The muscle cells that make up heart muscle tissue.

CARDIOMYOPATHY. Measurable deterioration of the heart muscle's ability to contract normally, eventually leading to heart failure.

CARNITINE. An amino acid necessary for metabolism of the long-chain fatty acid portion of lipids. Also called vitamin B7.

CARRIER. A person who possesses a gene for an abnormal trait without showing signs of the disorder. The person may pass the abnormal gene on to offspring.

CARRIER TESTING. Testing performed to determine whether someone possesses one changed copy and one unchanged copy of a particular gene.

CARTILAGE. Supportive connective tissue that cushions bone at joints or connects muscle to bone.

CARTILAGE OLIGOMERIC MATRIX PROTEIN GENE. A gene that codes for a specific protein involved in the formation of cartilage.

CASCADE TESTING. A term that refers to performing genetic counseling and testing in blood relatives of a person identified as having a specific genetic mutation. It is most commonly recommended for the relatives of patients carrying a genetic mutation linked to cancer.

CAT SCAN. Acronym for a computed axial tomography, a computerized x-ray examination of internal organs

CATABOLISM. The energy-releasing process of breaking down complex chemical compounds into simpler ones in the body.

CATAGEN. The breakdown phase of the hair growth cycle.

CATALYST. A substance that changes the rate of a chemical reaction but is not physically changed by the process.

CATALYZE. Facilitate. A catalyst lowers the amount of energy required for a specific chemical reaction to occur. Catalysts are not used up in the chemical reactions they facilitate.

CATAPLEXY. A symptom of narcolepsy in which there is a sudden episode of muscle weakness triggered by emotions. The muscle weakness may cause the person's knees to buckle, or the head to drop. In severe cases, the patient may become paralyzed for a few seconds to a few minutes.

CATARACT. A clouding of the eye lens or its surrounding membrane that obstructs the passage of light, resulting in blurry vision. Surgery may be performed to remove the cataract.

CATATONIA. Psychomotor disturbances that can include stupor, rigidity, muteness, purposeless, or bizarre movements; may occur with a severe ASD.

CATATONIC BEHAVIOR. Behavior characterized by muscular tightness or rigidity and lack of response to the environment.

CATECHOLAMINES. Biologically active compounds involved in the regulation of the nervous and cardiovascular systems, rate of metabolism, body temperature, and smooth muscle.

CATHETER. A narrow, flexible tube used to create a pathway for introducing drugs, nutrients, fluids, or blood products into the body and/or for removing fluid or other substances from the body.

CATHETERIZATION. The process of inserting a hollow tube into a body cavity or blood vessel.

CATIONIC TRYPSINOGEN GENE. A gene known to cause hereditary pancreatitis when significantly altered.

CAUDAL. Pertaining to the tail (bone).

CAUTERIZATION. Process of burning tissue either with a laser or electric needle to stop bleeding or destroy damaged tissue.

CAVEOLAE (SINGULAR, CAVEOLA). Tiny, flask-shaped pockets in the plasma membranes of human and animal cells.

CD4+ CELLS. A type of T cell that secretes small proteins (called cytokines) that regulate the body's active immune response to infections.

CD8+ CELLS. A type of T cell that kills cancer cells, cells infected with viruses, or cells that are damaged in other ways. CD81 cells are also known as cytotoxic T cells, killer T cells, and cytolytic T cells.

CDKN2A OR P16. Gene, when altered, known to cause Familial Atypical Multiple Mole Melanoma (FAMMM) syndrome and possibly increased pancreatic cancer risk.

CECUM. The first part of the large bowel.

CELL. The smallest living units of the body that group together to form tissues and help the body perform specific functions.

CELL ADHESION MOLECULE. Any one of several thousand proteins that together control the cell-to-cell communication that must take place in order for cells to migrate to their proper places, develop into the proper types of cells, and make the appropriate connections with other cells.

CELL DANGER RESPONSE (CDR). A metabolic response of cells to various types of threats.

CELL DIFFERENTIATION. The act of a cell becoming a specific type of cell.

CELL LINE. A defined population of cells that can be maintained in culture for an extended period of time while retaining stable phenotypes and functions. Cell lines can be either finite (lasting for a limited period of time due to cellular senescence) or immortal (able to divide and reproduce indefinitely in a suitable culture medium as a result of mutations).

CELLULAR IMMUNITY. A type of acquired immunity mediated by killer T-cells; important in fighting "hidden" infections, such as those caused by cellular parasites and some viruses.

CELLULAR SENESCENCE. The point at which cell division stops in an average cell, usually around 50 successive divisions. This stopping point is called the Hayflick limit.

CEMENTOMA. A type of noncancerous tumor that contains a bony substance known as cementum.

CENTRAL NERVOUS SYSTEM (CNS). In humans, the central nervous system is composed of the brain, the cranial nerves and the spinal cord. It is responsible for the coordination and control of all body activities.

CENTRAL POLYDACTYLY. Occurring between the thumb and little finger or between the big toe and the little toe.

CENTRAL VISION. The ability to see objects located directly in front of the eye. Central vision is necessary for reading and other activities that require people to focus on objects directly in front of them.

CENTROMERE. A constricted region of a chromosome that is involved in cell division and is used to define the long arm (q) and short arm (p) of the chromosome.

CEREBELLAR ATAXIA. Unsteadiness and lack of coordination caused by a progressive degeneration of the part of the brain known as the cerebellum.

CEREBELLAR TONSILS. Lobes on the undersurface of each hemisphere of the cerebellum.

CEREBELLUM. The part of the brain between the brain stem and back of the cerebrum, consisting of two lateral lobes and a median lobe and involved especially in muscle coordination and maintenance of equilibrium.

CEREBRAL AUTOSOMAL DOMINANT ARTERIOPATHY WITH SUBCORTICAL INFARCTS AND LEUKOENCEPHALOPATHY (CADASIL). An inherited type of vascular dementia.

CEREBRAL CORTEX. The outer surface of the cerebrum made up of gray matter and involved in higher thought processes.

CEREBRAL PALSY. Movement disability resulting from nonprogressive brain damage.

CEREBRAL VENTRICLES. Spaces in the brain that are located between portions of the brain and filled with cerebrospinal fluid.

CEREBRAL WHITE MATTER MIGRATION LINES. Pattern of defects found in the cerebral cortex of the brain probably caused by abnormal migration of neurons during brain formation.

CEREBRO-CEREBELLAR CIRCUITS. Neural pathways that originate in the cerebral cortex and travel through the deeper structures of the brain and back to the cerebral

cortex. They control verbal working memory and other higher-order brain functions.

CEREBROSIDES. Fatty carbohydrates that occur in the brain and nervous system.

CEREBROSPINAL FLUID (CSF). Clear fluid that circulates in the brain and spinal cord to nourish, cushion, and maintain uniform pressure.

CEREBRUM. The largest section of the brain, which is responsible for such higher functions as speech, thought, vision, and memory.

CEROID. The by-product of cell membrane breakdown.

CERULOPLASMIN. A protein circulating in the bloodstream that binds with copper and transports it.

CERVICITIS. Inflammation of the cervix.

CFTR. Cystic fibrosis transmembrane conductance regulator. The protein responsible for regulating chloride movement across cells in some tissues. When a person has two defective copies of the *CFTR* gene, cystic fibrosis is the result.

CHANNELOPATHY. A type of disease caused by disturbances in the function of ion channels or the proteins that regulate them. Channelopathies may be either genetic or acquired later in life.

CHAPERONIN. A molecule that captures and refolds misshapen proteins that might interfere with normal cellular functions; also called a protein cage.

CHELATION THERAPY. A form of therapy in which chelating agents are administered to remove heavy metals from the body. Chelating agents are chemicals that have a special affinity for metal ions. (Pronounced: key-LAY-shun.)

CHEMOTHERAPY. Treatment of cancer with synthetic drugs that destroy the tumor either by inhibiting the growth of the cancerous cells or by killing the cancer cells.

CHIARI II ANOMALY. A structural abnormality of the lower portion of the brain (cerebellum and brain stem) associated with spina bifida; the lower structures of the brain are crowded and may be forced into the foramen magnum, the opening through which the brain and spinal cord are connected.

CHILDHOOD DISINTEGRATIVE DISORDER. A type of ASD in which children develop normally until about age three or four and then, over a period of a few months, lose their previously learned motor, language, social, and other skills.

CHOANAL ATRESIA. A bony or membranous blockage of the passageway between the nose and pharynx at birth.

CHOLELITHIASIS. The formation of gallstones within the gallbladder.

CHOLESTEROL. A fatty-like substance that is obtained from the diet and produced by the liver. Cells require cholesterol for their normal daily functions.

CHOLINESTERASE INHIBITORS. Drugs that may slow the progression of Alzheimer's disease by inhibiting the enzymes that break down the neurotransmitter acetylcholine.

CHONDROCYTE. A specialized type of cell that secretes the material that surrounds the cells in cartilage.

CHONDRODYSTROPHY. A general term for any of several disorders of the skeleton caused by mutations that affect the normal development of cartilage.

CHONDROSARCOMA. A malignant tumor derived from cartilage cells.

CHOREA. An involuntary movement disorder characterized by short, jerky motions of the body.

CHOREOATHETOSIS. Involuntary rapid, irregular, jerky movements or slow, writhing movements that flow into one another.

CHORIOCAPILLARIS. Capillary layer of the choroid.

CHORION. The outer membrane of the amniotic sac. Chorionic villi develop from its outer surface early in pregnancy. The villi establish a physical connection with the wall of the uterus and eventually develop into the placenta.

CHORIONIC VILLUS. Cells that are present in the placenta that can be used for genetic analysis.

CHORIONIC VILLUS SAMPLING (CVS). A procedure used for prenatal diagnosis at 10–12 weeks gestation. Under ultrasound guidance a needle is inserted either through the mother's vagina or abdominal wall and a sample of cells is collected from around the early embryo. These cells are then tested for chromosome abnormalities or other genetic diseases.

CHOROID. A vascular membrane that covers the back of the eye between the retina and the sclera and serves to nourish the retina and absorb scattered light.

CHOROID PLEXUS. Specialized structures located in the ventricles of the brain that produce cerebrospinal fluid.

CHROMATID. Each of the two strands formed by replication (copying) of a chromosome; chromatids are held together by the centromere, which subsequently divides and

separates the two chromatids to form two new chromosomes.

CHROMATIN. A complex found in mammalian cells consisting of DNA, protein, and RNA. Chromatin serves to package DNA into a smaller volume that will fit within the cell to prevent damage to DNA and to control DNA replication and gene expression. It condenses to form chromosomes during the process of cell division.

CHROMOSOMAL ABERRATIONS. A general term for abnormalities in either the number or the structure of chromosomes.

CHROMOSOMAL ANEUPLOIDY. A condition in which the chromosomal number is either increased or decreased.

CHROMOSOMAL DELETION. Loss of a segment of DNA from a chromosome.

CHROMOSOMAL MICROARRAY (CMA) TESTING. A prenatal genetic test used to diagnose microdeletion syndromes and some aneuploidies. It consists of DNA samples from the patient and a reference source that have been labeled with fluorescent dyes and allowed to hybridize or bind to the synthetic DNA on the glass or plastic chip. The chip is then scanned by a computer to determine whether the patient's DNA binds to the normal DNA sequence or whether it binds to the sequence representing a DNA mutation.

CHROMOSOME. A microscopic threadlike structure found within each cell of the body that consists of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Changes in either the total number of chromosomes or their shape and size (structure) may lead to physical or mental abnormalities.

CHROMOSOME DELETION. A missing sequence of DNA or part of a chromosome.

CHROMOSOME INVERSION. Rearrangement of a chromosome in which a section of a chromosome breaks off and rejoins the chromosome upside down.

CHROMOSOME TRANSLOCATION. The exchange of genetic material between chromosomes, which can lead to extra or missing genetic material.

CHRONIC ATROPHIC GASTRITIS. Irritation and breakdown of the stomach wall over a period of time.

CHRONIC MYELOGENOUS LEUKEMIA (CML). A type of leukemia caused by the BCR-ABL oncogene created by a gene fusion formed by a chromosomal translocation.

CHYLOMICRON. A type of lipoprotein made in the small intestine and used for transporting fats to other tissues in the body. MTP is necessary for the production of chylomicrons.

CILIARY BODY. A structure within the eye that produces aqueous humor.

CILIOPATHY. A range of genetic disorders caused by mutations in cellular cilia, basal bodies, or by changes in ciliary function.

CILIUM. A slender protuberance from a larger cellular body. Required for sensing environmental and chemical stimuli, controlling signaling and developmental pathways. Plural: cilia.

CIRCUMCISION. The surgical removal of the foreskin of the penis.

CIRCUMFERENCE. The length around a circle.

CIRRHOISIS. A chronic degenerative disease of the liver in which normal cells are replaced by fibrous tissue. Cirrhosis is a major risk factor for the later development of liver cancer.

CLASS I MHC. Includes *HLA-A*, *HLA-B*, and *HLA-C*. Important in cellular immunity.

CLASS II MHC. *HLA-DP*, *HLA-DQ*, and *HLA-DR*. Important in humoral immunity.

CLASS III MHC. Includes the complement system.

CLAUDICATION. Pain in the lower legs after exercise caused by insufficient blood supply.

CLAVICLE. Also called the collarbone. Bone that connects the shoulder and the breast bone.

CLEFT. An elongated opening or slit in an organ.

CLEFT LIP. A separation of the upper lip that is present from birth but originates early in fetal development. A cleft lip may appear on one side (unilateral) or both sides (bilateral) and is occasionally accompanied by a cleft palate. Surgery is needed to completely repair cleft lip.

CLEFT PALATE. A congenital malformation in which there is an abnormal opening in the roof of the mouth that causes improper connection of the nasal passages and the mouth.

CLICKWRAP AGREEMENT. An online agreement between a user and a company in which users must click a box or button and read the agreement before they download content, make a purchase, or use a website.

CLINICAL BREAST EXAM (CBE). Examination of the breasts, performed by a physician or nurse.

CLINICAL LABORATORY IMPROVEMENT AMENDMENTS (CLIA). A set of regulations passed in 1988 that establish federal standards applicable to all laboratories or sites that test human specimens for health assessment or to diagnose, prevent, or treat disease.

CLINODACTYLY. A birth defect in which a finger (most often the little finger) is bent at an angle toward the neighboring finger (usually the fourth finger).

CLITORIS. A small mass of erectile tissue in the female genitalia.

CLONUS. Involuntary rhythmic muscular contractions and relaxations.

CLOVERLEAF SKULL. An abnormal, or cloverleaf, appearance to the skull caused by premature fusion of the bones in the skull of an infant.

CLUBFOOT. Abnormal permanent bending of the ankle and foot. Also called *talipes equinovarus*.

CLUTCH. The name for a group of eggs laid by zebrafish, other fish, amphibians, or birds.

COAGULATION. The process by which a liquid becomes a solid, as in blood clotting.

COAGULOPATHY. A disorder in which blood is either too slow or too quick to coagulate (clot).

COBB ANGLE. A measure of the curvature of scoliosis, determined by measurements made on x-rays.

COCHLEA. A bony structure shaped like a snail shell located in the inner ear. It is responsible for changing sound waves from the environment into electrical messages that the brain can understand, so people can hear.

COCHLEAR IMPLANTATION. A surgical procedure in which a small electronic device is placed under the skin behind the ear and is attached to a wire that stimulates the inner ear, allowing people who have hearing loss to hear useful sounds.

CO-DOMINANT. Describes the state when two alleles of the same gene are both expressed when inherited together.

CODON. A sequence of three nucleotides that code for specific amino acids.

CO-ENZYME. A small molecule such as a vitamin that works together with an enzyme to direct a biochemical reaction within the body.

COFACTOR. A substance that is required by an enzyme to perform its function.

COGNITIVE. Of, relating to, or involving conscious mental activities (such as thinking, understanding, learning, and remembering).

COGNITIVE-BEHAVIORAL THERAPY (CBT). A type of psychotherapy that teaches people to recognize and change negative patterns of thinking and behavior.

COHESINOPATHY. A condition, such as Cornelia de Lange syndrome, that affects the cohesion complex that separates chromosomes during cell division.

COLCHICINE. A compound that blocks the assembly of microtubules, which are protein fibers necessary for cell division and some kinds of cell movements, including neutrophil migration. Side effects may include diarrhea, abdominal bloating, and gas.

COLECTOMY. Surgical removal of the colon.

COLITIS. Inflammation of the colon.

COLLAGEN. The main structural protein found in the various types of connective tissue in humans and other animals. It is found in skin, ligaments, tendons, cartilage, and the intervertebral disks in the spine. Disorders of collagen are called collagenopathies.

COLOBOMA. A birth defect in which part of the eye does not form completely and appears to be cleft or notched.

COLON. The large intestine.

COLONOSCOPY. An examination of the rectum and colon with a long flexible instrument passed through the anus; also used to obtain biopsy samples.

COLORECTAL. Of the colon and/or rectum.

COLOSTOMY. The creation of an artificial opening into the colon through the skin for the purpose of removing bodily waste. Colostomies are usually required because key portions of the intestine have been removed.

COMBINED FIRST-TRIMESTER SCREENING. Blood tests for pregnancy-associated plasma protein A and human chorionic gonadotropin and an ultrasound exam for chromosomal abnormalities.

COMMON RULE. A federal policy for the protection of human research subjects in any study funded by the U.S. government; it was first defined in 1981 and amended in 2018. Formally stated in the Code of Federal Regulations, Title 45, Part 46, the Common Rule requires informed consent from all research subjects and the oversight of every study by an institutional review board (IRB).

COMPANION DIAGNOSTIC TEST. A test that provides information about the safety and efficacy of a corresponding medication. Some liquid biopsies are companion diagnostic tests.

COMPLEMENT SYSTEM. Part of the innate immune system that helps clear pathogens from an organism. It stimulates a cascade of enzyme activity that effectively lyses cells/pathogens open that are marked for destruction.

COMPLEMENTARY DNA (CDNA). DNA that is transcribed (copied) from messenger RNA using the enzyme reverse transcriptase.

COMPLETE BLOOD COUNT (CBC). A measurement of blood levels of red blood cells, white blood cells, and platelets.

COMPLETE PENETRANCE. Condition in which all who carry the gene display some symptoms.

COMPLETE SITUS INVERSUS. A laterality defect resulting in a mirror image of the normal organ formation with heart, spleen, and stomach on the right side, and the liver and gallbladder on the left.

COMPOUND HETEROZYGOTE. Having two different mutated versions of a gene.

COMPUTED TOMOGRAPHY (CT) SCAN. An imaging procedure that produces a three-dimensional picture of organs or structures inside the body, such as the brain.

COMPUTERIZED AXIAL TOMOGRAPHY (CAT) SCAN. An imaging technique that visualizes organs or tissues.

COMPUTERIZED TOMOGRAPHY (CT). A technique that uses a beam of radiation and a computerized analysis to produce an image of a body structure, often the brain.

COMT INHIBITORS. Drugs that block catechol-O-methyltransferase, an enzyme that breaks down dopamine. COMT inhibitors include entacapone and tolcapone.

CONCEPTUS. The products of conception, or the union of a sperm and egg cell at fertilization.

CONDUCTIVE HEARING LOSS. Hearing loss that is the result of a dysfunction of the parts of the ear responsible for collecting sound. In this type of hearing loss, the auditory nerve is generally not damaged.

CONES. Receptor cells that allow the perception of colors.

CONFETTI SKIN LESIONS. Numerous light or white spots seen on the skin that resemble confetti.

CONGENITAL. Occurring at or before birth.

CONGENITAL ANOMALY. An abnormality that is present at birth.

CONGENITAL BILATERAL ABSENCE OF VAS DEFERENS (CBAVD). The absence at birth of the vas deferens on each side of the male reproductive tract.

CONGENITAL CATARACT. Clouding of the lens in the eye that is present at birth.

CONGENITAL DISORDER OF DEGLYCOSYLATION (CDDG). NGLY1 deficiency or N-glycanase 1 deficiency,

in which sugar chains cannot be removed from misfolded proteins so that they can undergo degradation; caused by mutations in the NGLY1 gene.

CONGENITAL DISORDER OF GLYCOSYLATION (CDG). A family of genetic disorders that includes NGLY1 deficiency (congenital disorder of deglycosylation), as well as disorders in which sugars are not properly attached to proteins (glycosylation).

CONGENITAL HYPOPLASTIC ANEMIA (CHA). A significant reduction in the number of red blood cells present at birth, usually referring to deficient production of these cells in the bone marrow. Also sometimes called congenital aplastic anemia.

CONGENITAL MALFORMATION. A birth defect or physical abnormality present at birth.

CONNECTIVE TISSUE. A group of tissues responsible for support throughout the body; includes cartilage, bone, fat, tissue underlying skin, and tissues that support organs, blood vessels, and nerves throughout the body.

CONOTRUNCAL HEART ABNORMALITY. Congenital heart defects particularly involving the ventricular (lower chambers) outflow tracts of the heart includes subarterial ventricular septal defect, pulmonic valve atresia and stenosis, tetralogy of Fallot and truncus arteriosus.

CONSANGUINEOUS. Sharing a common bloodline or ancestor.

CONSANGUINITY. The property of belonging to the same blood kinship as another person. In genetics, marriages between two people who are second cousins or closer are regarded as consanguineous unions.

CONTIGUOUS GENE SYNDROME (CGS). An older term for microdeletion syndromes in which several genes lying closely together on the chromosome are lost as a group.

CONTINENCE. Normal function of the urinary bladder and urethra, allowing fluid flow during urination and completely stopping flow at other times.

CONTRACTURE. A tightening of muscles that prevents normal movement of the associated limb or other body part.

CONVULSION. Involuntary contractions of body muscles that accompany a seizure episode.

COPROLALIA. The involuntary expression of obscene words or phrases.

COPROPORPHYRIN. Excrement in the urine or feces indicative of unused porphyrin in the body due to overaccumulation of porphyrin.

COPROPAXIA. The involuntary display of unacceptable/obscene gestures.

COPY NUMBER VARIATION (CNV). A difference in the number of copies of a gene (normally two) or of a specific segment of DNA.

CORDOCENTESIS. A prenatal diagnostic test, usually done between 16 and 30 weeks of gestation. Using ultrasound guidance, a thin needle is introduced through the abdomen into the amniotic sac. A blood sample is taken directly from the umbilical cord. Tests can then be done on the blood sample.

CORNEA. The transparent structure of the eye over the lens that is continuous with the sclera in forming the outermost protective layer of the eye.

CORNEAL. Pertaining to the cornea of the eye, which is the clear covering that protects the front of the eyeball.

CORNEAL TRANSPLANT. Removal of impaired and diseased cornea and replacement with corneal tissue from a recently deceased person.

CORONAL SUTURE. The skull suture that lies behind the forehead area, across the head from the left side to the right side.

CORPUS CALLOSUM. A thick bundle of nerve fibers deep in the center of the forebrain that provides communication between the right and left cerebral hemispheres.

CORTICAL TUBER. Round (nodular) growth found in the cortex of the brain.

CORTICAL-THALAMIC CIRCUITS. A circular connection within the brain that travels between the cerebral cortex and the thalamus and back to the cerebral cortex. Scientists believe it helps the brain monitor its status.

CORTICOSPINAL TRACT. A bundle of long nerve fibers that runs from the motor control region of the cerebral cortex to the spinal cord, where it connects to nerves that control movement in the legs.

CORTICOSTEROIDS. Anti-inflammatory medications. They are related to cortisol, a naturally produced hormone that controls many bodily functions.

CORTISOL. Hydrocortisone; a glucocorticoid hormone produced by the adrenal glands that mediates various metabolic process and responds to stress; deficient in congenital adrenal hypoplasia.

COXA VARA. A deformed hip joint in which the neck of the femur is bent downward.

CRANIAL SUTURE. Any one of the seven fibrous joints between the bones of the skull.

CRANIOFACIAL. Relating to or involving both the head and the face.

CRANIOPAGUS. Conjoined twins with separate bodies and one shared head.

CRANIOSYNOSTOSIS. A condition in which one or more of the fibrous joints (sutures) in an infant's skull turns to bone prematurely. As a result, the shape of the head is affected as the infant continues to grow, and the facial features are often deformed.

CRANIUM. The skeleton of the head, which include all of the bones of the head except the mandible.

CREATINE KINASE (CK). An enzyme found in the brain, heart, and skeletal muscles; if elevated amounts are discovered, it can indicate the presence of one of several serious medical conditions.

CREATININE. A normal component of blood kept in low levels in urine by functioning kidneys.

CREUTZFELDT-JAKOB DISEASE (CJD). A degenerative disease of the central nervous system caused by an abnormal protein called a prion.

CRISPR (CLUSTERED REGULARLY INTERSPERSED SHORT PALINDROMIC REPEATS). A technique for genome editing that involves creating a short RNA sequence called guide RNA (gRNA) that matches a targeted sequence of DNA in the organism's genome. The gRNA guides an enzyme called Cas9 to the target DNA sequence. The enzyme cuts the genome at this location, and the researcher can either remove DNA, add new DNA, or modify the DNA.

CROHN'S DISEASE. A chronic inflammatory autoimmune disease similar to colitis.

CROUZON SYNDROME. A genetic disorder that is similar to Crouzonodermoskeletal syndrome but without acanthosis nigricans.

CRYPTOPHTHALMOS. A congenital malformation of the eye in which the eyelid fails to develop, the eye is either missing or rudimentary, and the orbit of the eye is covered by a fold of skin extending directly from the forehead to the cheek.

CRYPTORCHIDISM. A condition in which one or both testes fail to descend normally.

CURETTAGE. A surgical scraping or cleaning.

CUTANEOUS. Of, pertaining to, or affecting the skin.

CUTANEOUS SYNDACTYLY. Fusion of the soft tissue between fingers or toes resulting in a webbed appearance.

CYANOSIS. A bluish color of the skin that results from insufficient oxygen in the blood transported throughout the body.

CYANOTIC. Marked by bluish discoloration of the skin due to a lack of oxygen in the blood. It is one of the types of congenital heart disease.

CYCLOOXYGENASE-2 (COX-2) INHIBITORS. Anti-inflammatory drugs that work by blocking the COX-2 enzyme, which plays a role in the inflammatory process. COX-2 inhibitors do not block the COX-1 enzyme, which helps protect the digestive tract.

CYST. An abnormal sac or closed cavity filled with liquid or semi-solid matter.

CYSTIC FIBROSIS (CF). A respiratory disease characterized by chronic lung disease, pancreatic insufficiency, and an average age of survival of 20 years. Cystic fibrosis is caused by mutations in a gene on chromosome 7 that encode a transmembrane receptor.

CYSTIC HYGROMA. An accumulation of fluid behind the fetal neck, often caused by improper drainage of the lymphatic system in utero.

CYSTINE. A sulfur-containing amino acid, sometimes found as crystals in the kidneys or urine, that forms when proteins are broken down by digestion.

CYTOGENETICS. The branch of genetics that studies the components of a cell associated with heredity, particularly the chromosomes.

CYTOGENIC. Pertaining to the production of cells.

CYTOKINE. A protein associated with inflammation that, at high levels, may be toxic to nerve cells in the developing brain.

CYTOPLASM. The substance within a cell, including the organelles and the fluid surrounding the nucleus.

CYTOSKELETON. The network of proteins underlying and maintaining the integrity of the red blood cell membrane.

D

DANDY-WALKER MALFORMATION. A complex structural abnormality of the brain frequently associated with hydrocephalus, or accumulation of excess fluid in the brain. Abnormalities in other areas of the body may also be present. Individuals with Dandy-Walker malformation have varying degrees of mental handicap or none at all.

DEBRANCHING ENZYME. Enzyme responsible for breaking down the branched structure of glycogen stores to release glucose into the bloodstream.

DEBULKING. The removal of abnormal tissue.

DECIBEL (DB). A logarithmic unit for expressing loudness or intensity; normal speech is typically in the range of 20–50 dB.

DECIDUOUS TEETH. The first set of teeth or “baby teeth.”

DECREASED PENETRANCE. Individuals who inherit a changed disease gene, but do not develop symptoms.

DEEP VEIN THROMBOSIS. A blood clot in one of the systemic veins deep in the body.

DEFICIENCY OF ADENOSINE DEAMINASE 2 (DADA2). Syndromes caused by mutations in the *CECR1* gene.

DEFORMATION. An abnormal form or position of a part of the body caused by extrinsic pressure or mechanical forces.

DEGENERATIVE DISC DISEASE. Narrowing of the disc space between the spinal bones (vertebrae).

DEGRADATION. Lost or diminished function.

DE GROUCHY SYNDROME. Deletions in chromosome 18, originally identified in the 1960s by the French geneticist Jean de Grouchy.

DEHYDRATION. An extreme loss of water in the body, which, if untreated, can lead to brain damage and death.

DELAYED BONE AGE. An abnormal condition in which the apparent age of the bones, as seen in x-rays, is less than the chronological age of the patient.

DELETION. A mutation resulting in the loss of normal base pair sequence; a deletion may be of any size from one base pair to most of a chromosome.

DELTA-F508. The most common cystic fibrosis-causing mutation in Caucasians, resulting in a defective CFTR protein due to the deletion of the amino acid phenylalanine (F) at amino-acid position 508 of the protein.

DELUSION. A fixed, false belief that is resistant to reason or factual disproof.

DEMENTIA. A group of disorders and symptoms that impact memory, reasoning, social abilities, and intellectual functioning and that impair the ability to function normally in daily life.

DENDRITIC CELLS (DCS). Accessory cells in the mammalian immune system that acts as messengers between the adaptive and innate immune systems. Their name is derived from their tree-like shape.

DE NOVO MUTATION. A genetic mutation that is seen for the first time in the affected person, not inherited from the parents.

DENTAL AGENESIS. Failure of the teeth to form normally during embryonic development. The complete absence of all the teeth is called anodontia.

DENTAL PITS. Small, shallow holes or crevices in the tooth enamel.

DENTIN. A hard, calcareous material that covers the tooth root and, in turn, is covered by cementum and enamel.

DEOXYRIBONUCLEIC ACID (DNA). The genetic material in cells that carries the inherited instructions for growth, development, and cellular functioning.

DEPIGMENTATION. Loss of pigment or skin color.

DEPOLARIZATION. The dissipation of an electrical charge through a membrane. In the heart, depolarization causes the heart muscle to contract.

DEPOT DOSAGE. A form of medication that can be stored in the patient's body tissues for several days or weeks, thus minimizing the risk of the patient forgetting daily doses.

DERMABRASION. Scraping or sanding the epidermal layer of the skin to remove scars and other marks or wrinkles.

DERMATOLOGIC. Pertaining to the field of dermatology, the science of the skin and diseases that affect the skin.

DERMATOLOGIST. A physician who specializes in disorders of the skin.

DERMATOSPARAXIS. Skin fragility caused by abnormal collagen.

DERMIS. The layer of skin beneath the epidermis.

DESCMET'S MEMBRANE. Sheet of tissue that lies under the stroma and protects against infection and injuries.

DESFEROXAMINE. The oldest of three drugs used in iron chelation therapy. It aids in counteracting the life-threatening buildup of iron in the body associated with long-term blood transfusions.

DESMOID TUMOR. A benign, firm mass of scar-like connective tissue.

DESMOPRESSIN (DDAVP). A drug used in the treatment of von Willebrand's disease.

DEVELOPMENT. The process whereby undifferentiated embryonic cells replicate and differentiate into limbs, organ systems, and other body components of the fetus.

DEVELOPMENTAL DELAY. When children do not reach certain milestones at appropriate ages. For example, a

child should be able to speak by the time he or she is five years old.

DEVELOPMENTAL MILESTONES. Infants and toddlers develop skills at certain ages. For example, by nine months, a child should be able to grasp and toss a bottle.

DEXTROCARDIA. Right-sided positioning of the heart.

DFN2 OR DFNX1. A DeaFNess gene locus associated with nonsyndromic, progressive, X-linked hearing loss, now identified as the *PRPS1* gene locus.

DIABETES. An inability to control the levels of sugar in the blood due to an abnormality in the production of, or response to, the hormone insulin.

DIABETES INSIPIDUS. A disorder caused by insufficient secretion of vasopressin (antidiuretic hormone or ADH) or failure of the kidneys to respond to vasopressin, with symptoms similar to those of diabetes mellitus; it may be inherited, especially in children.

DIABETES MELLITUS. The clinical name for common diabetes. It is a chronic disease characterized by inadequate production or use of insulin.

DIABETIC KETOACIDOSIS (DKA). A life-threatening complication of diabetes mellitus.

DIAGNOSTIC TESTING. Testing performed to determine if someone is affected with a particular disease.

DIALYSIS. Filtering of blood to remove waste products that the kidneys would normally remove if they were present and functioning.

DIAPHRAGM. Dome-shaped muscle and fiber that separates the torso into two sections, thoracic and abdominal.

DIAPHRAGMATIC HERNIA. An abnormal opening in the diaphragm, the layer of muscle that separates the chest cavity from the abdominal cavity.

DIAPHYSIS. The middle portion, or shaft, of a long bone.

DIARRHEA. Loose, watery stool.

DIASTOLIC BLOOD PRESSURE. Blood pressure when the heart is resting between beats.

DICEPHALUS. Conjoined twins who share one body but have two separate heads and necks.

DIFFERENTIATE. Specialized development to perform a particular function.

DIGENIC INHERITANCE. A pattern of inheritance in which mutations in two (and only two) different genes are required for the manifestation of a genetic disorder.

FSHD type 2 is an example of a genetic disorder with digenic inheritance.

DIGESTIVE ENZYME. Proteins secreted by the pancreas that enter the small intestine and break down food so it can be absorbed by the body.

DIGIT. A finger or toe.

DIHYDROTESTOSTERONE (DHT). A male sex hormone formed from testosterone by the enzyme 5-alpha-reductase. DHT causes hair follicles to shut down, shortening the growth phase of the hair growth cycle and leading to miniaturization.

DILATED CARDIOMYOPATHY. A diseased and weakened heart muscle that is unable to pump blood efficiently.

DIOPTER (D). A unit of measure for describing refractive power.

DIPLEGIA. Paralysis affecting like parts on both sides of the body, such as both arms or both legs.

DIPLOID. Referring to a cell or nucleus that contains two copies of genetic material, or a complete set of chromosomes.

DISRUPTION. A type of anomaly formation in which a breakdown or inhibition of normal tissue development occurs.

DISTAL. Away from the point of origin.

DISTAL 18Q. A deletion of the end of the long arm of chromosome 18, including the tip.

DISTAL ARTHROGRYPOSIS. A disorder characterized by contractions of the muscles in the hands.

DISTAL MUSCLES. Muscles that are farthest away from the center of the body.

DIURETICS. Medications that increase the excretion of urine.

DIVERGENT STRABISMUS. Eyes that point in different directions due to imbalanced eye muscles.

DIVERTICULAE. Sacs or pouches in the walls of a canal or organ. They do not normally occur, but may be acquired or present from birth. Plural form of diverticula.

DIZYGOTIC. From two zygotes, as in nonidentical, or fraternal, twins. The zygote is the first cell formed by the union of sperm and egg.

DNA (DEOXYRIBONUCLEIC ACID). The genetic material that contains the instructions for creating proteins.

DNA BASE. One unit in a DNA sequence. The four DNA bases are adenine (A), guanine (G), thymine (T) and

cytosine (C). The sequence of these bases is the genetic code which contains the instructions for creating proteins.

DNA FINGERPRINTING. A laboratory technique used to identify individuals by extracting and identifying base-pair patterns in a person's DNA. Originally developed to solve crimes or identify human remains, DNA fingerprinting has been used to detect cross-contamination in cell lines since the early 1990s.

DNA METHYLATION. The addition of methyl groups (CH³) to nucleotide bases of DNA to regulate gene expression.

DNA MISMATCH REPAIR. A system for recognizing and replacing wrongly paired (mismatched) nucleotide bases during DNA replication. The system can also repair some forms of DNA damage.

DNA MUTATION ANALYSIS. A direct approach to the detection of a specific genetic mutation or mutations using one or more laboratory techniques.

DNA POLYMERASE. An enzyme that is required for DNA replication. It functions in the addition of new nucleotides in the production of new DNA strands.

DNA REPEATS. A three-letter section of DNA called a triplet, which is normally repeated several times in a row. Too many repeats often cause the gene to malfunction, resulting in disease.

DNA REPLICATION. The process in which a DNA molecule forms two identical copies of itself.

DNA SEQUENCE. The sequence of DNA bases that contains the instructions for creating proteins. A three-base sequence in the DNA contains the instructions for making a particular amino acid. For example, CGC codes for the amino acid alanine. Proteins are made up of one or more amino acids strung together. The instructions for a particular protein are made up of a number of three base sequences. Because DNA is double-stranded, it has two complementary sequences where the bases pair up together. C always pairs with G, and A always pairs with T. One example of double-stranded DNA sequence for alanine is GCG/CGC.

DNA TESTING. Analysis of DNA (the genetic component of cells) in order to determine changes in genes that may indicate a specific disorder.

DNA VIRUS. A virus whose genetic material is deoxyribonucleic acid (DNA). The instructions from DNA are transcribed into RNA. Some common DNA viruses are herpesvirus, papillomavirus, and parvovirus.

DOLICOCEPHALY. Elongated and narrow skull shape due to premature closure of the sagittal suture that runs from the forehead to the back of the skull.

DOMINANT. A genetic trait that is expressed when only one copy of it is present.

DOMINANT INHERITANCE. A type of genetic inheritance pattern that results in one form of a gene being dominant over other forms. Therefore, the dominant allele can express itself and cause disease, even if only one copy is present.

DOMINANT PROGRESSIVE HEARING LOSS (DPHL). The most common type of hereditary nonsyndromic progressive sensorineural hearing loss.

DOMINANT TRAIT. A genetic trait where one copy of the gene is sufficient to yield an outward display of the trait; dominant genes mask the presence of recessive genes; dominant traits can be inherited from a single parent.

DONOR RECRUITMENT AND TISSUE COLLECTION CENTERS (DRTCCS). Several locations designated for identifying and enrolling donors and acquiring multiple tissue samples from each, using best practices for sample collection, handling, fixation, and storage.

DOPAMINE. A neurochemical made in the brain that is involved in many brain activities, including movement and emotion.

DOPAMINE RECEPTOR ANTAGONISTS (DAS). The older class of antipsychotic medications, also called neuroleptics, which primarily block the site on nerve cells that normally receive the brain chemical dopamine.

DORSAL ANTERIOR CINGULATE CORTEX (DACC). An area of the cerebral cortex that is involved in fear, mood disorders, and PTSD.

DORSAL RHIZOTOMY. A surgical procedure that cuts nerve roots to reduce spasticity in affected muscles.

DORSAL ROOT GANGLIA. The subset of neuronal cells controlling impulses in and out of the brain.

DOWNSHOOT. Downward movement of the eye.

DOWN SYNDROME. Trisomy 21, a genetic disorder caused by all or part of an extra chromosome 21; characterized by intellectual disability, characteristic facial features, and various other developmental defects.

DRPLA. Dentatorubral-pallidoluysian atrophy; also called Haw River syndrome and Natito-Oyanagi disease. DRPLA is a disorder of ataxia, choreoathetosis, and dementia in adults, and ataxia, myoclonus, epilepsy, and intellectual disability in children.

DRUG METABOLISM. Chemical modification or breakdown of drugs. This usually occurs through the activity of specialized enzymatic pathways.

DRUSEN. Fatty deposits that can accumulate underneath the retina and macula and sometimes lead to AMD. Drusen formation can disrupt the photoreceptor cells, which causes central and color vision problems for people with dry AMD.

DUCT. A tube-like structure that carries secretions from glands.

DUCTUS. The blood vessel that joins the pulmonary artery and the aorta. When the ductus does not close at birth, it causes a type of congenital heart disease called patent ductus arteriosus.

DUCTUS ARTERIOSUS. The temporary channel or blood vessel between the aorta and pulmonary artery in the fetus.

DUODENUM. Portion of the small intestine nearest the stomach; the first of three parts of the small intestine.

DUPLICATION. A mutation in which part of the chromosome is repeated, adding extra genetic material.

DURA MATER. A thick membrane that is the outermost of the three layers of tissue (meninges) covering the brain and spinal cord. Tissue from this membrane has been used for transplantation in cases of head trauma but is now considered a risk factor for iatrogenic CJD.

DWARFISM. In general, a condition in which a person is considerably shorter than normal when fully grown (below an adult height of 4 feet 10 inches) as a result of an endocrine disorder, skeletal abnormality, or genetic disorder. There are about 200 different conditions that can cause dwarfism.

DYSARTHRIA. Refers to a group of speech disorders caused by disturbances in the strength or coordination of the muscles of the speech mechanism as a result of damage to the brain or nerves.

DYSKINESIA. Impairment or difficulty in performing voluntary movements, usually resulting in jerky or interrupted movements.

DYSMORPHIC. An abnormal body structure often associated with a genetic disorder.

DYSOSTOSIS. A general term for a disorder of bone development.

DYSOSTOSIS MULTIPLEX. A variety of bone and skeletal malformations.

DYSPHAGIA. Difficulty in swallowing.

DYSPHORIA. Feelings of anxiety, restlessness, and dissatisfaction.

DYSPLASIA. Abnormal development of tissues, organs, or cells.

DYSPLASTIC. Describing the abnormal growth or development of a tissue or organ.

DYSPNEA. Shortness of breath or difficulty in breathing.

DYSTHYMIA. A psychological condition of chronic depression that is not disabling but prevents the sufferer from functioning at his or her full capacity.

DYSTONIA. A movement disorder involving prolonged muscle contractions that cause twisting and repetitive movements or abnormal posture.

DYSTOPIA CANTHORUM. A wide spacing between the inner corners of the eyes, with the eyes themselves having normal spacing. Also called telecanthus.

DYSTROPHIN. A protein that supports muscle strength. Its absence or insufficiency is one of the basic causes of muscular dystrophy.

DYSTROPHY. Progressive abnormal changes in a tissue or organ.

E

EAR TAGS. Excess pieces of skin on the outside of the ear.

EARLY-ONSET AD. Alzheimer's disease that develops between the ages of 30 and 60.

E-CADHERIN/CDH1. A gene involved in cell-to-cell connection. Alterations in this gene have been found in several families with increased rates of gastric cancer.

ECCRINE. Pertaining to the sweat glands located over most of the human body. Their water-based sweat is the primary mechanism of cooling in humans.

ECHOCARDIOGRAM (ECHO). A diagnostic procedure that uses sound waves to produce images of the heart.

ECHOCARDIOGRAPH. A record of the internal structures of the heart obtained from beams of ultrasonic waves directed through the wall of the chest.

ECHOLALIA. Involuntary echoing of the last word, phrase, or sentence that is spoken by someone else or by sounds in the environment.

ECHOPRAXIA. The imitation of the movement of another individual.

ECLABIUM. Outward turning of the lip.

ECLAMPSIA. The onset of seizures in a pregnant woman with pre-eclampsia, a condition characterized by protein in the urine, high blood pressure, and sometimes other organ dysfunction.

ECTODERM. The outermost of the three embryonic germ layers, which later gives rise to the nervous system, skin, hair, teeth, and nails.

ECTODERMAL DYSPLASIA. A hereditary condition that results in the malformation of the skin, teeth, and hair. It is often associated with malfunctioning or absent sweat glands and/or tear ducts.

ECTOPIC. Tissue found in an abnormal location.

ECTRODACTYLY. A birth defect involving a split or cleft appearance of the hands and/or feet, also referred to as a "lobster-claw" malformation.

ECTROPION. An abnormal turning out, as of the eyelid.

ECZEMA. Inflammation of the skin with redness and other variable signs such as crusts, watery discharge, and itching.

EDEMA. An abnormal accumulation of fluid beneath the skin and in the cavities of the body.

EDWARDS SYNDROME. Trisomy 18; a genetic disorder caused by an extra chromosome 18 that can be screened for in the first trimester.

EFFLUVIUM. The medical term for massive hair loss or shedding.

ELASTIC FIBER. Fibrous, stretchable connective tissue made primarily from proteins, elastin, collagen, and fibrillin.

ELECTROCARDIOGRAM (ECG, EKG). A test that uses electrodes attached to the chest with an adhesive gel to transmit the electrical impulses of the heart muscle to a recording device.

ELECTROCONVULSIVE THERAPY. A treatment in which a series of controlled electrical impulses are delivered to the brain in order to induce a seizure.

ELECTRODESSICATION AND CURETTAGE. A procedure by which a papula is cut out of the skin (curettage) and bleeding controlled with an electric current (electrodesiccation).

ELECTRODESSICATION. A surgical technique for removing skin cancers by drying out tissue with an electric current and then removing the dead tissue with a curette.

ELECTROENCEPHALOGRAM (EEG). A test that measures the electronic waves of the brain.

ELECTROLYTE. A solution or a substance in a solution consisting of various chemicals that can carry electric charges. Electrolytes exist in the blood as acids, bases, and salts, such as sodium, calcium, potassium, chlorine, and magnesium.

ELECTROMYOGRAPHY (EMG). A test that uses electrodes to record the electrical activity of muscle. The information gathered is used to diagnose neuromuscular disorders.

ELECTRORETINOGRAM (ERG). A measurement of electrical activity of the retina.

ELECTRORETINOGRAPHY (ERG). A diagnostic test that records electrical impulses created by the retina when light strikes it.

EMBOLIZATION. A technique for treating some types of bleeding disorders or cancer by blocking blood vessels.

EMBOLIZATION THERAPY. Introduction of a coil or various substances into blood vessels in order to plug them and stop excessive bleeding.

EMBRYO. The earliest stage of development of a human infant, usually used to refer to the first eight weeks of pregnancy. The term “fetus” is used from roughly the third month of pregnancy until delivery.

EMBRYOGENESIS. The formation and growth of the embryo.

EMBRYOLOGY. The study of the growing embryo.

EMBRYONIC STEM CELLS (ESCS). Cells from early-stage embryos that have the capacity to differentiate into any cell type (pluripotency).

EMOLLIENT. Petroleum- or lanolin-based skin lubricants.

EMPHYSEMA. A chronic lung disease that begins with breathlessness during exertion and progresses to shortness of breath at all times, caused by destructive changes in the lungs.

EMPIRICAL. Relying on, or derived from, observations gained through the senses or by experimentation.

ENAMEL. The hard, white coating that covers teeth. Enamel is the hardest material in the body.

ENCAPSULATED. Referring to bacteria that have a thick capsule protecting their cell wall.

ENCEPHALITIS. Inflammation of the brain.

ENCEPHALOCELE. A congenital anomaly in which part of the brain is herniated through the skull.

ENCEPHALOPATHY. The medical term for any global dysfunction of the brain. It is not a single disease but rather a syndrome that has many different causes and prognoses.

ENCHONDROMAS. Benign cartilaginous tumors arising in the cavity of bone. They have the possibility of causing lytic destruction within the bone.

ENDOCARDIAL FIBROELASTOSIS (EFE). An abnormal thickening of the lining of the heart tissue due to a concentration of elastic collagen-like fibers.

ENDOCARDITIS. A dangerous infection of the heart valves caused by certain bacteria.

ENDOCRINE GLAND. Any gland that secretes its products directly into the bloodstream rather than through a duct. The hypothalamus, pituitary, and thyroid are all endocrine glands.

ENDOCRINE SYSTEM. A system of ductless glands that regulate and secrete hormones directly into the bloodstream.

ENDOLYMPH. The fluid in the inner ear.

ENDOMETRIUM. Lining of the uterus.

ENDONUCLEASE. Enzymes that recognize short pieces of DNA (often palindromic) and cleave either within or near the recognized sequence.

ENDOPLASMIC RETICULUM. A network of tubules and flattened sacs that serve a variety of functions within a cell, ranging from protein transport to the synthesis of carbohydrate and fat molecules.

ENDOPLASMIC RETICULUM-ASSOCIATED DEGRADATION (ERAD). An important cellular pathway that includes N-glycanase 1 and is responsible for breaking down (degrading) misfolded glycoproteins.

ENDOSCOPE. A slender, tubular optical instrument used as a viewing system for examining an inner part of the body. With an attached instrument, the endoscope can be used for biopsy or surgery.

ENDOSCOPIC MUCOSAL RESECTION. Removal of the mucosa during endoscopy.

ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY (ERCP). A method of viewing the pancreas by inserting a thin tube down the throat into the pancreatic and bile ducts, injecting dye, and performing x rays.

ENDOSTEAL. Relating to the endosteum, which is the lining of the medullary cavity.

ENDOTHELIAL CELLS. The cells lining the inner walls of the blood vessels.

ENDOTHELIUM. Extremely thin innermost layer of the cornea.

END-STAGE RENAL DISEASE (ESRD). A potentially fatal condition that occurs when the kidneys can no longer effectively filter urine and excrete waste products from the body.

ENERGY HOMEOSTASIS. The ability of all living things to maintain energy balance.

ENHANCER. A DNA sequence that binds transcription factors to promote gene activity (transcription).

ENLARGED VESTIBULAR AQUEDUCT (EVA). An enlargement of a structure inside the inner ear called the vestibular aqueduct, which is a narrow canal that allows fluid to move within the inner ear. EVA is seen in approximately 10% of people who have sensorineural hearing loss.

ENTEROCOLITIS. Severe inflammation of the intestines that affects the intestinal lining, muscle, nerves, and blood vessels.

ENTEROSCOPY. A procedure used to examine the small intestine.

ENTHESITIS. Inflammation at the place where the ligaments insert into the bone.

ENTHESOPATHY. Disorder of the ligament attachment to the bone.

ENZYME. A protein that catalyzes a biochemical reaction or change without changing its own structure or function.

ENZYME EFFICIENCY. The rate at which an enzyme can perform the chemical transformation it is expected to accomplish. This is also called turnover rate.

ENZYME REPLACEMENT THERAPY (ERT). A treatment method used to replace missing enzymes. It is possible to synthesize enzymes and then inject them intravenously into patients.

EPENDYMOMA. A tumor of the central nervous system derived from cells that line the central canal of the spinal cord and the ventricles of the brain.

EPICANTHAL FOLD. A wrinkle in the skin extending from the nose up to the eyebrow; it is sometimes associated with genetic anomalies.

EPIDERMIS. The outermost layer of the skin.

EPIDERMOID CYST. A benign, cystic tumor derived from epithelial cells.

EPIDIDYMIS. A system of ducts emerging posteriorly from the testes that holds sperm during maturation and that forms a tangled mass before uniting into a single coiled duct that is continuous with the vas deferens.

EPIGENETIC. A modification to DNA, such as the addition of a methyl group, that does not change the DNA sequence.

EPIGENETICS. The study of how behaviors and environmental factors can lead to changes in how genes work. The changes are reversible and do not alter the DNA sequence.

EPIGENOME. All of the molecules that are added to DNA molecules to regulate the activity of genes without changing the DNA sequence.

EPI-LASIK. A surgical procedure that uses a blunt, plastic oscillating blade called an epithelial separator to cut a flap in the cornea.

EPILEPSY. Recurrent seizures that temporarily affect awareness, movements, sensations or consciousness; sometimes associated with ASD.

EPIPHYSEAL. The region of the bone responsible for growth of the bone.

EPIPHYSES. The growth areas at the end of bones. (Singular: epiphysis.)

EPISTAXIS. The medical term for nosebleed.

EPITHELIAL CELLS. The layer of cells that cover the open surfaces of the body such as the skin and mucous membranes.

EPITHELIUM. The layer of cells that cover the open surfaces of the body such as the skin and mucous membranes.

EPITOPE. The specific piece of an antigen that an antibody binds to.

EPSTEIN SYNDROME. A subgroup of the *MYH9*-related disorders characterized by the platelet disorder, kidney disease, and hearing loss.

EPSTEIN-BARR VIRUS (EBV). A human herpesvirus (HHV-4) that causes infectious mononucleosis and is associated with certain types of cancer and complications of HIV infection.

EQUAL EMPLOYMENT OPPORTUNITY COMMISSION (EEOC). The U.S. Government agency charged with enforcing Title II of GINA, which covers employment discrimination.

ERYTHEMA NODOSUM LEPROSUM. A complication of leprosy characterized by development of small, painful

swellings due to inflammation of a blood or lymph vessel. It is often accompanied by inflammation of a nerve or nerves, causing decreased function of the affected area.

ERYTHROBLAST. The immediate precursor of a normal red blood cell.

ERYTHROCYTE. The scientific name for a normal mature red blood cell. Erythrocytes do not contain cell nuclei.

ERYTHROPOIESIS. The process through which new red blood cells are created; it begins in the bone marrow.

ERYTHROPOIETIC. Referring to the creation of new red blood cells.

ESCHARS. Painful patches of dead, blackened tissue.

ESOPHAGUS. The part of the digestive tract that connects the mouth and stomach; the food pipe.

ESOTROPIA. A form of strabismus in which one or both eyes turns inward.

ESTROGEN. A female sex hormone.

ETHICS. The branch of philosophy dealing with questions of good and evil, and with moral duties and obligations in human society.

ETIOLOGY. The cause of a disease, syndrome, or anomaly.

EUGENICS. A set of beliefs and practices intended to improve the genetic quality of a country's human population, either by limiting the reproduction of people considered unfit or by encouraging the reproduction of healthier, more intelligent, and more attractive people.

EUSTACHIAN TUBE. Small tube that connects the middle ear to the throat.

EUTHYROID. Having normal thyroid gland function.

EVOKED RESPONSE TESTS. Tests that measure the speed of brain connections.

EXCISION. Surgical removal.

EXOCRINE PANCREAS. The secreting part of the pancreas.

EXOME. The protein-encoding DNA sequences (exons) of the genome.

EXOMPHALOS. An umbilical protrusion or hernia.

EXON. The expressed portion of a gene. The exons of genes are those portions that actually chemically code for the protein or polypeptide that the gene is responsible for producing.

EXOPHTHALMOS. The bulging of the eye forward from the orbit. It is a symptom of abnormally high levels of thyroid hormone.

EXOSOMES. Very small (between 30 and 150 nanometers in diameter) vesicles secreted by various types of cells that contain proteins, nucleic acids, or other biomolecules. Exosomes are of particular interest in liquid biopsy, because they can be found in blood, urine, and cerebrospinal fluid and thus may serve as biomarkers.

EXOSTOSIS. An abnormal growth (benign tumor) on a bone.

EXOTROPIA. A form of strabismus where the eyes are deviated outward.

EXPANSION. A genetic abnormality caused by a sequence of nucleotides that is repeated too many times in a section of a gene.

EXPRESSION QUANTITATIVE TRAIT LOCI (EQTL). Locations within the genomic loci that contribute to expression of mRNAs.

EXTERNAL MEATUS. The external opening through which urine and seminal fluid (in males only) leave the body.

EXTRA-INTESTINAL. Outside of the intestine.

EXTRAOCULAR MUSCLE FIBROSIS. Abnormalities in the muscles that control eye movement.

EXTRAPYRAMIDAL SYMPTOMS (EPS). A group of side effects associated with antipsychotic medications, including parkinsonism, akathisia, dystonia, and tardive dyskinesia.

EXTRAPYRAMIDAL. Refers to brain structures located outside the pyramidal tracts of the central nervous system.

EXUDATE. Fluid that accumulates and penetrates the walls of vessels, leaking into the surrounding tissue.

EX VIVO. The gene therapy is done on cells that are outside of the body.

F

FACIAL ANGIOFIBROMAS. Benign (noncancerous) tumors of the face.

FA CORE COMPLEX. A group of eight proteins encoded by FA genes that function as part of the FA pathway in DNA repair. The FA core complex has been described as a cellular "machine" for DNA repair.

FACTOR VIII. A protein involved in blood clotting that requires VWF for stability and long-term survival in the bloodstream.

FACTORS. Coagulation factors are substances in the blood, such as proteins and minerals, that are necessary for clotting. Each clotting substance is designated with roman numerals I through XIII.

FAILURE TO THRIVE. Significantly reduced or delayed physical growth.

FALLOPIAN TUBE. Either of a pair of tubes that conduct ova from the ovaries to the uterus.

FALSE NEGATIVE. A test result that indicates that a disease or condition is not present when it really is; sometimes called a type II error.

FALSE POSITIVE. A test result that indicates that a person has a disease or condition when they do not; it is sometimes called a type I error.

FAMILIAL. An inherited disease affecting multiple family members.

FAMILIAL ADENOMATOUS POLYPOSIS (FAP). An inherited syndrome causing large numbers of polyps and increased risk of colon cancer and other cancers.

FAMILIAL GASTRIC CANCER. Gastric cancer that occurs at a higher rate in some families.

FAMILIAL IDIOPATHIC BASAL GANGLIA CALCIFICATION (FIBGC). Fahr disease or primary familial brain calcification (PFBC).

FANCONI SYNDROME. A disorder of reabsorption in the kidney tubules.

FA PATHWAY. The biological process that is activated when DNA replication is shut down by interstrand cross-links and other types of DNA damage.

FASTING BLOOD GLUCOSE TEST (FGT). A diabetes test that measures blood glucose after an eight-hour fast.

FATTY ACIDS. The primary component of fats (lipids) in the body. Carnitine palmitoyl transferase (CPT) deficiency involves abnormal metabolism of the long-chain variety of fatty acids.

FBN2. The gene that encodes fibrillin-2; mutations in this gene can cause congenital contractural arachnodactyly.

FECAL OCCULT BLOOD TEST. Study of stool (feces) to identify loss of blood in the gastrointestinal system.

FECHTNER SYNDROME. A subgroup of the *MYH9*-related disorders characterized by the platelet disorder

and inclusion bodies in the white blood cells, kidney disease, hearing loss, and cloudiness of the eye.

FERRITIN. An intracellular protein that stores iron and releases it in a controlled manner. Ferritin in blood plasma is an indirect marker of the total amount of iron stored in the body.

FERTILE. Able to reproduce.

FERTILITY FRAUD. A recently coined term for physicians' use of their own sperm in assisted reproductive techniques.

FERTILITY TOURISM. The practice of traveling to another jurisdiction or country for fertility treatments unavailable or illegal in one's own country.

FETAL AKINESIA. A condition in which lack of fetal movement (akinesia) during pregnancy results in musculoskeletal abnormalities, underdevelopment of the lungs, and/or misshapen facial features. Fetal akinesia can result from a variety of conditions, ranging from abnormalities in the structure of the mother's uterus to infections or genetic disorders that affect fetal development.

FETAL ALCOHOL SYNDROME. Syndrome characterized by distinct facial features and varying mental retardation in an infant due to impaired brain development resulting from the mother's consumption of alcohol during pregnancy.

FETAL ECHOCARDIOGRAM. A detailed ultrasound of the fetal heart usually performed between 18 and 24 weeks of gestation.

FETAL FRACTION. The proportion of cell-free DNA in a pregnant woman's blood that comes from the placenta. The fetal fraction should be above 4% for the most accurate results.

FETAL HYDROPS. A condition in which there is too much fluid in the fetal tissues, fetal cavities, or both.

FETOSCOPE. A tubular instrument that can be inserted into the abdomen and uterus and used to visualize a fetus during pregnancy.

FETUS. The term used to describe a developing human from approximately the third month of pregnancy until delivery. The term "embryo" is used prior to the third month.

FETUS IN FETU. A fetus growing inside the body of the other twin.

FGFR2 AND FGFR3. The genes encoding fibroblast growth factor receptors 2 and 3; mutations in these genes can cause Crouzon syndrome.

FGFR-RELATED CRANIOSYNOSTOSIS. A group of eight disorders including Pfeiffer syndrome, Apert syndrome, Crouzon syndrome, Beare-Stevenson syndrome, *FGFR2*-related isolated coronal synostosis, Jackson-Weiss syndrome, Crouzon syndrome with acanthosis nigricans (AN), and Muenke syndrome (isolated coronal synostosis) all caused by a mutation of an *FGFR* gene.

FIBRILLATION. A rapid, irregular heartbeat.

FIBRILLIN. A glycoprotein secreted by fibroblasts into the extracellular matrix necessary for the deposition of elastin and the proper function of elastic fibers found in connective tissues.

FIBRILLIN-2. A protein that helps form microfibrils that provide strength and flexibility to connective tissue.

FIBRIN. The final substance created through the clotting cascade, which provides a strong, reliable plug to prevent further bleeding from the initial injury.

FIBRINOGEN. A fibrous protein that circulates in blood and participates in blood clotting by attaching to platelets.

FIBROBLAST. A cell that forms connective tissue fibers such as skin.

FIBROBLAST GROWTH FACTOR RECEPTOR GENE. A type of gene that codes for a cell membrane receptor involved in normal bone growth and development.

FIBROBLAST GROWTH FACTORS (FGFs). A family of proteins that signal through growth factor receptors to regulate cell division, cell proliferation, and wound healing in humans and many other species.

FIBROFOLLICULOMA. Small, white or yellow, dome-shaped benign growths on hair follicles.

FIBROID. A noncancerous tumor of connective tissue made of elongated, threadlike structures, or fibers, which usually grow slowly and are contained within an irregular shape. Fibroids are firm in consistency but may become painful if they start to break down or apply pressure to areas within the body. They frequently occur in the uterus and are generally left alone unless growing rapidly or causing other problems. Surgery is needed in order to remove fibroids.

FIBROMA. A nonmalignant tumor of connective tissue.

FIBROMATOSIS. The medical term for a group of conditions marked by benign soft-tissue tumors that are aggressive, infiltrate other tissues, and frequently recur even though they are not cancerous. HDD is sometimes categorized as a type of fibromatosis.

FIBROSIS. The abnormal development of fibrous tissue; scarring.

FINASTERIDE. An oral medication used to treat male pattern hair loss. Finasteride, sold under the trade names Proscar and Propecia, is an androgen inhibitor.

FINE NEEDLE ASPIRATION (FNA). Insertion of a thin needle through the skin to an area of sample tissue.

FIRST-DEGREE RELATIVE. A parent, child, or sibling is a first-degree relative. First-degree relatives have one half of their genes in common.

FIRST-RANK SYMPTOMS. A set of symptoms designated by Kurt Schneider in 1959 as the most important diagnostic indicators of schizophrenia: delusions, hallucinations, thought insertion or removal, and thought broadcasting.

FISTULA. An abnormal connection between two hollow body organs or spaces.

FITZPATRICK PHOTOTYPE SCALE. A set of six skin types based on the skin's response to the ultraviolet radiation in sunlight. The scale was devised in 1975 by Thomas Fitzpatrick, a dermatologist at Harvard University. Fitzpatrick types I and II are at the greatest risk of melanoma.

FLEXION CREASES. The lines on the palms of the hands and the soles of the feet from normal bending of these body parts. Some individuals affected with arthropoysis lack these characteristic lines.

FLOW CYTOMETRY. A method of analyzing cells in which cell properties are detected as they flow in a narrow stream through a measuring device.

FLUORESCEIN ANGIOGRAPHY. Procedure to look at the blood vessel system of the eye. Fluorescein, a dye, is injected and photographs are taken as the dye passes through the eye's blood vessels.

FLUORESCENCE IN SITU HYBRIDIZATION (FISH). A laboratory technique for detecting and identifying a specific sequence of DNA on a chromosome. The researcher designs a probe, which is a small DNA sequence that contains a fluorescent molecule. The probe then binds to its corresponding sequence on the chromosome.

FLUOROCHROME. A fluorescent compound used for visualization in FISH.

FOCAL SEGMENTAL GLOMERULOSCLEROSIS (FSGS). Formation of scar tissue in the filtering unit of the kidney. "Focal" means that only some of the glomeruli are affected; "segmental" means that only a segment or section of an affected glomerulus is damaged.

FOCAL SEIZURE. A seizure that causes a brief and temporary change in movement, sensation, or nerve function.

FOLATE-SENSITIVE FRAGILE SITE. A chromosome location that, under folate-deficient conditions, appears as a gap in a chromosome and is susceptible to breakage.

FOLLICLE. A pouch-like depression.

FOLLICLE-STIMULATING HORMONE (FSH). A hormone that stimulates estrogen production in females and sperm production in males.

FONTANELLE. One of several “soft spots” on the skull where the developing bones of the skull have yet to fuse.

FOOT DROP. A gait abnormality in which the affected person cannot raise the toes and front of the foot, or raise the foot at the ankle. Foot drop is an indication of a disease of the muscles or nerves; it is not a disease in itself.

FORAMEN. A small opening or hole in a body part or tissue.

FORAMEN MAGNUM. The round opening at the base of the skull through which the spinal cord passes to join the spine.

FOREBRAIN. The anterior of the front section of the brain.

FOREHEAD PLAQUE. Flat, fibrous skin growth on the forehead.

FORENSIC. Pertaining to the use of science or medicine in the investigation and establishment of evidence in a court of law.

FOUNDER EFFECT. Increased frequency of a gene mutation in a population that was founded by a small ancestral group of people, at least one of whom was a carrier of the gene mutation.

FRAGILE X SYNDROME. A genetic condition caused by a mutation in the *FMRI* gene on the X chromosome and characterized by intellectual disability.

FRAGILE X TREMOR/ATAXIA SYNDROME (FXTAS). A movement disorder caused by 55–200 CGG repeats in the *FMRI* gene.

FRONTAL BOSSING. The medical term for an unusually prominent forehead, typically accompanied by a heavy brow ridge.

FRONTAL LOBE. Region of the brain located in the frontal and upper cortex, it is responsible for higher mental functions like critical thinking and decision making.

FRONTAL PLAGIOCEPHALY. An abnormal condition of the skull in which the front is more developed on one side than it is on the other side.

FRONTONASAL DYSPLASIA (FND). A congenital malformation of the face characterized by wide, flat nose; abnormally widely spaced eyes; and a cleft that runs down the middle of the face across the nose.

FRONTOTEMPORAL DISORDERS (FTD). Various types of dementia that affect the frontal and temporal lobes of the brain; FTDP-17 is a rare inherited FTD.

FUNCTIONAL MAGNETIC RESONANCE IMAGING (FMRI). A form of imaging of the brain that registers blood flow to functioning areas of the brain.

FUNDUS. The interior back wall of the eyeball.

G

G-6-P DEFICIENCY. An X-linked genetic disorder that predisposes patients to the spontaneous destruction of red blood cells in response to certain triggers that include certain foods, medications, and illnesses. It is caused by a mutation on the X chromosome at Xq28.

GABAERGIC SYSTEM. The system by which gamma-aminobutyric acid (GABA), the main neuro-inhibitory transmitter and its receptor, function within the brain during pre- and post-synaptic events to modulate ion channels.

GAIN-OF-FUNCTION MUTATION. A mutation that results in enhanced or new activity on a protein. Loss-of-function mutations are more common.

GAIT. A person’s habitual pattern of walking, or the pattern of movement of his or her lower limbs.

GAIT DISTURBANCES. Disturbances that affect the manner of walking.

GALACTOSE. One of the two simple sugars, together with glucose, that makes up the protein lactose, found in milk. Galactose can be toxic in high levels.

GALACTOSEMIA. A rare genetic disorder in which the person cannot metabolize galactose, a simple sugar found in dairy products.

GALLBLADDER. A small, pear-shaped organ in the upper right hand corner of the abdomen. It is connected by a series of ducts (tube-like channels) to the liver, pancreas, and duodenum (first part of the small intestine). The gallbladder receives bile from the liver and concentrates and stores it. After a meal, bile is squeezed

out of the gallbladder into the intestine, where it aids in digestion of food.

GAMETE. Reproductive cells of an organism that fuse together during fertilization.

GAMMA AMINO BUTYRIC ACID (GABA). An amino acid that functions as the major inhibitory neurotransmitter in the nervous system.

GAMMA KNIFE. Equipment that precisely delivers a concentrated dose of radiation to a predetermined target using gamma rays.

GANGLIOSIDE. A complex membrane lipid made up of a long-chain fatty acid, a long-chain amino alcohol, and an oligosaccharide containing sialic acid.

GANGRENE. Death of tissue due to deficient or absent blood supply.

GARDNER SYNDROME. A term that is sometimes used for patients with familial adenomatous polyposis (FAP) who have desmoid tumors in the tissues covering the colon in addition to polyps inside the colon.

GASTRIC. Associated with the stomach.

GASTRIC TUBE. A tube that is surgically placed through the skin of the abdomen to the stomach so that feeding with nutritional liquid mixtures can be accomplished.

GASTROENTEROLOGIST. A physician who specializes in disorders of the digestive system.

GASTROESOPHAGEAL REFLUX. The return of the contents of the stomach back up into the esophagus.

GASTROINTESTINAL. Concerning the stomach and intestine.

GASTROINTESTINAL (GI) SYSTEM. The body system involved in digestion, the breaking down and use of food.

GASTROINTESTINAL REFLUX DISEASE (GERD). A chronic condition, usually accompanied by heartburn, that can damage the esophagus.

GASTROINTESTINAL TRACT. The food intake and waste export system that runs from the mouth, through the esophagus, stomach, and intestines, to the rectum and anus.

GASTROSCHISIS. A small defect in the abdominal wall normally located to the right of the umbilicus, and not covered by a membrane, where intestines and other organs may protrude.

GASTROSTOMY. The construction of an artificial opening from the stomach through the abdominal wall to permit the intake of food.

GAUCHER DISEASE. A genetic disorder characterized by the accumulation of fatty substances in certain cells and organs. It is caused by a mutation in a gene on chromosome 1 and is inherited in an autosomal recessive pattern. It is named for the French physician Philippe Gaucher, who first described it in 1882.

GAVAGE. Feeding tube.

GENE. A building block of inheritance that contains the instructions for the production of a particular protein and is made up of a molecular sequence found on a section of DNA. Each gene is found at a precise location on a chromosome.

GENE AMPLIFICATION. The creation of multiple copies of a gene, which can result in the production of excessive amounts of a specific protein.

GENE EDITING. is a process that involves changing an organism's DNA by removing, adding, or changing it.

GENE EXPRESSION. The process in which a gene is transcribed into mRNA, and then translated into a protein. Multiple methods of regulation are used by cells to tightly control the levels of gene expression.

GENE EXPRESSION PANEL. A method for genetically characterizing specific types of cancer.

GENE MUTATION. A permanent change in genetic material that is transmittable.

GENE SEQUENCING. The process of mapping the order of DNA or genetic material in an organism.

GENE THERAPY. Replacing a defective gene with a normal copy.

GENEALOGY. The study or investigation of a person's lineage or family tree.

GENERATION TIME. The average length of time elapsed between two consecutive generations in an animal population. The generation time for zebrafish is about three months.

GENETIC ANTICIPATION. The tendency for an inherited disease to become more severe in successive generations.

GENETIC BIOMARKER. A variant in DNA, RNA, or protein that can be measured and is an indicator of disease. These biomarkers can be used to assess the expression, function, or regulation of a gene.

GENETIC CODE. A set of instructions for transferring genetic data stored in the form of DNA or RNA into proteins.

GENETIC COUNSELING. A short-term educational counseling process for individuals and families who have a genetic disease or who are at risk for such a disease. Genetic counseling provides patients with information about their condition and helps them make informed decisions.

GENETIC COUNSELOR. A health professional with advanced training in genetics and psychology who educates people about genetic conditions and testing.

GENETIC DISCRIMINATION. Discrimination against people in employment or health insurance on the basis of their genetic information, including genetic testing results or a family medical history that suggests genetic predisposition to a disease.

GENETIC DISEASE. A disease that is (partly or completely) the result of the abnormal function or expression of a gene; a disease caused by the inheritance and expression of a genetic mutation.

GENETIC DRIFT. Variations in gene frequency within a population due to chance rather than mutation or natural selection.

GENETIC HETEROGENEITY. The production of apparently identical genetic disorders by different genetic mechanisms or by different genes at different positions on the chromosomes.

GENETIC LOCUS. The specific location of a gene on a chromosome.

GENETIC MARKER. A DNA or RNA sequence variant. In plant breeding, markers can be linked to particular plant characteristic (traits).

GENETIC MOSAICISM. A mixture of cells of two or more genotypes.

GENETIC SEX. The gender determined by the sex chromosomes. XX is female; XY is male.

GENETIC TEST. Testing of chromosomes and genes from an individual or unborn baby for a genetic condition. Genetic testing can only be done if the gene is known.

GENETIC TESTING. Testing of chromosomes and genes from an individual or unborn baby for a genetic condition. Genetic testing can only be done if the gene is known.

GENETICIST. A specialist (MD or PhD) who has training and certification in diagnosing, managing, and counseling individuals/families with genetic disorders. Genetic counselors hold a master's degree in medical genetics and provide many of the same services as geneticists.

GENITAL HYPOPLASIA. Underdeveloped genitals.

GENITAL TRACT. The organs involved in reproduction. In a male, they include the penis, testicles, prostate, and various tubular structures to transport seminal fluid and sperm. In a female, they include the clitoris, vagina, cervix, uterus, fallopian tubes, and ovaries.

GENITALIA. The organs of reproduction.

GENITOURINARY. Related to the reproductive and urinary systems of the body.

GENOME. The total amount of genetic information within an organism's chromosomes, including its genes and DNA sequences.

GENOME EDITING. A technique used by researchers to change the sequence of genetic material, for example, the DNA, of an organism. It can be used to fix a pathogenic mutation that can cause disease.

GENOME-WIDE ASSOCIATION STUDY (GWAS). A method for identifying genes involved in human disease by searching a number of human genomes for small variations that occur more commonly in people with a given disease than in those who do not have the disease.

GENOMIC SELECTION. A method in plant breeding that predicts the value of breeding stock based on genetic information.

GENOMICS. The study of the structure, function, and evolution of genomes and how they interact with each other and the environment.

GENOTYPE. The complete set of an organism's genetic material. The term is sometimes used to refer to the genes or set of genes for a single trait, such as height or eye color.

GERM CELLS. The cells that create the egg and sperm cells (gametes).

GERM LINE. The population of a complex organism's cells that pass on genetic information to offspring. Germline cells include eggs, sperm, and fertilized eggs.

GERM-LINE MOSAICISM. A rare event that occurs when one parent carries an altered gene mutation that affects his or her germ-line cells (either the egg or sperm cells) but is not found in the somatic (body) cells.

GERM-LINE MUTATION. A heritable change in the DNA of a germ cell (a cell destined to become an egg or in the sperm). When passed from one generation to the next, a germ-line mutation is incorporated in every cell of the body.

GERM-LINE RETINOBLASTOMA. A type of retinoblastoma where all cells of the body have a variant in one

copy of the *RBI* gene. This can be inherited or result early in the development of the embryo.

GESTATIONAL AGE. An estimation of the age of a pregnancy. The beginning of gestation or pregnancy is counted from the first day of the woman's last menstrual period, although conception usually takes place about two weeks later.

GESTATIONAL DIABETES MELLITUS (GDM). Diabetes that develops during pregnancy and increases the risk of type 2 diabetes.

GIEMSA STAIN. A nucleic acid stain used to band chromosomes and to make a karyogram or map of chromosomes. The stain is named for Gustav Giemsa (1867–1948), the German pharmacist and bacteriologist who devised the stain in 1904.

GINGIVAL. Pertaining to the gums. Gingival fibromatosis refers to an overgrowth of the tissue of the gums.

GINGIVAL FIBROMAS. Fibrous growths found on the gums.

GINGIVITIS. Inflammation of the gums of the mouth, characterized by redness, swelling, and a tendency to bleed.

GLAUCOMA. A group of eye disorders resulting in damage to the optic nerve, in most cases as the result of increased intraocular pressure (fluid pressure within the eye). Untreated glaucoma can result in permanent loss of vision.

GLIAL CELLS. Supportive cells for nerve cells in the brain and spinal cord.

GLIOBLASTOMA MULTIFORME. A tumor of the central nervous system consisting of undifferentiated glial cells.

GLIOMA. A tumor of the brain's glial cells.

GLOBIN. One of the component protein molecules found in hemoglobin. Normal adult hemoglobin has a pair each of alpha-globin and beta-globin molecules.

GLOBOZOOSPERMIA. A genetic condition in which sperm have round heads and lack acrosomes, among other defects, resulting in male infertility.

GLOBUS PALLIDUS. A small paired structure present in the deep portion of the brain, in front of the brain stem, that is considered a part of the basal ganglia and helps in movement control.

GLOMERULI. The tiny networks of capillaries in the nephrons (filtering units) of the kidneys that serve to filter the blood during the first stage of urine formation.

GLOSSOPTOSIS. Downward displacement or retraction of the tongue.

GLUCOCEREBROSIDE. A cerebroside that contains glucose in the molecule.

GLUCOCORTICOIDS. Corticosteroids, such as cortisol and dexamethasone, that regulate metabolism, along with other functions; medications used to treat congenital adrenal hyperplasia.

GLUCOSE. One of the two simple sugars, together with galactose, that makes up the protein lactose, found in milk. Glucose is the form of sugar that is usable by the body to generate energy.

GLYCINE. An amino acid (a building block of proteins) that is important in the transmission of nerve impulses.

GLYCOGEN. The chemical substance used by muscles to store sugars and starches for later use. It is composed of repeating units of glucose.

GLYCOGENESIS. The metabolic process responsible for the formation of glycogen from many glucose molecules.

GLYCOGENOLYSIS. The metabolic process responsible for the breakdown of glycogen to mobilize glucose.

GLYCOLYSIS. The pathway in which a cell breaks down glucose into energy.

GLYCOPROTEIN. A protein with at least one carbohydrate group.

GLYCOPROTEIN IIB/IIIA (GP IIB/IIIA). Sugar-proteins on the surface of platelets that bind to the fibrous protein, fibrinogen. These sugar-proteins are defective in Glanzmann's thrombasthenia.

GLYCOSYLPHOSPHATIDYLINOSITOL (GPI). A molecule that attaches proteins to the membranes of cells.

GOITER. A swelling of the neck or larynx caused by enlargement of the thyroid gland.

GOLGI APPARATUS. An organelle within cells that packages proteins for secretion outside the cell. Also called the Golgi body, it is named for the Italian physician Camillo Golgi, who first identified it in 1897.

GOLTZ SYNDROME. Focal dermal hypoplasia (FDH).

GONAD. The sex gland in males (testes) and females (ovaries).

GONADOTROPHIN. Hormones that stimulate the ovary and testicles.

GONADOTROPHIN-RELEASING HORMONE (GNRH).

The hormone produced by the hypothalamus that stimulates the release of gonadotropins such as luteinizing hormone (LH) and follicle-stimulating hormone (FSH).

GONIOSCOPE.

An instrument used to examine the trabecular meshwork; it consists of a magnifier and a lens equipped with mirrors.

GOWERS' SIGN.

An indication of weakness in the proximal muscles of the legs. The child has to use his hands and arms to rise from a squatting or kneeling position.

GRADE.

As a noun: a classification of the cancerous qualities of an individual tumor. A higher grade indicates a more serious disease than does a lower grade. As a verb: to classify the cancerous qualities of an individual tumor.

GRAFT-VERSUS-HOST DISEASE.

In bone marrow transplantation, the complication that occurs when the donor's cells attack the recipient's tissues, in part due to non-identical donor-recipient HLA types.

GRAND MAL SEIZURE.

A seizure that causes a loss of consciousness, a loss of bladder control, generalized muscle contractions, and tongue biting.

GRANULOCYTOPENIA.

A reduced number of white blood cells in the circulation.

GRANULOMA.

A group of noncancerous, nodular cells that form as a result of inflammation in the tissue.

GRANULOMATOSIS WITH POLYANGITIS.

Permanent enlargement of parts of the airways of the lung.

GRAY MATTER.

Areas of the brain and spinal cord that are made up mostly of unmyelinated nerves.

GREAT TOE.

The first and largest toe on the foot.

GRIEF REACTION.

The normal sadness felt after a traumatic major life occurrence, such as the loss of a loved one.

GROWTH FACTORS.

Cellular-signaling components that stimulate cell division or other cell processes.

GROWTH HORMONE (GH).

A hormone that stimulates growth. Also called somatotropin.

G-TUBE.

A gastrostomy tube, which is inserted surgically into the stomach and used for feeding and for administering medications.

GUIDE RNA (GRNA).

A combined tracer RNA and spacer RNA (pre-crRNA) that, when used in conjunction

with a Cas9 nuclease (crRNA), can target and cut specific DNA sequences.

GUSTATORY LACRIMATION.

Abnormal development of the tear ducts causing tears when chewing.

H**HALF-LIFE.**

The amount of time that it takes for a drug, cell, or other component of blood to drop to half of its initial value.

HALLUCINATION.

A sensory experience of something that does not exist outside the mind.

HALLUX.

The great toe.

HAMARTOMA.

An overgrowth of normal tissue.

HAMARTOMATOUS RECTAL POLYPS.

Benign (non-cancerous) growths found in the rectum.

HAPLOID.

Referring to cells that have only one chromosome of each type, and therefore have only one complete set of genes. Gametes (sperm and eggs) normally have a haploid number of chromosomes.

HAPLOINSUFFICIENCY.

The lack of one of the two normal copies of a gene. Haploinsufficiency can result in a genetic disorder if normal function requires both copies of the gene. Haploinsufficiency is one explanation for a dominant pattern of inheritance.

HAPLOTYPE.

A set of alleles that are inherited together as a unit on a single chromosome because of their close proximity.

HAYFLICK LIMIT.

The number of times (usually around 50) that a normal differentiated human cell will divide before its telomeres shorten to a critical length and cell division stops. The limit is named for Leonard Hayflick, an American professor of anatomy who first described it in 1961.

HB BART'S SYNDROME.

The form of alpha thalassemia most likely to cause hydrops fetalis in the fetus. The name of the syndrome refers to a defective type of hemoglobin (Hb) that has almost no ability to carry oxygen to the fetus's tissues and to the hospital in London (St. Bartholomew's, or Bart's) where the syndrome was first identified.

HEAD TURN.

Habitual head position that has been adopted to compensate for abnormal eye movements.

HEALTH INSURANCE PORTABILITY AND ACCOUNTABILITY ACT (HIPAA). A 1996 federal statute that includes a privacy rule regulating the use and disclosure of

protected health information (PHI). DTC genetic testing is not subject to HIPAA privacy regulations.

HEARING LEVEL (HL). Hearing threshold; the sound level that can just barely be heard.

HEART ARRHYTHMIA. An abnormal heart rhythm, in which the heartbeats may be too slow, too rapid, too irregular, or too early.

HELICASE. An enzyme, such as BLM, that unwinds and separates DNA during replication (chromosome copying prior to cell division).

HELICOBACTER PYLORI (H. PYLORI). A bacterium that infects humans and may be associated with an increased risk of gastric cancer.

HELLER'S SYNDROME. Another name for Childhood Disintegrative Disorder (CDD). It is also sometimes called dementia infantilis.

HELPER T-CELL. Specialized white blood cell that assists in humoral and cellular immunity.

HEMANGIOBLASTOMA. A tumor of the brain or spinal cord arising in the blood vessels of the meninges or brain.

HEMANGIOMA. Benign tumor made up of clusters of newly formed blood vessels.

HEMATIN. A drug administered intravenously to halt an acute porphyria attack. It causes heme biosynthesis to decrease, preventing the further accumulation of heme precursors.

HEMATOLOGY. The branch of medicine that deals with the diagnosis and treatment of diseases of the blood and bone marrow.

HEMATOMA. An accumulation of blood, often clotted, in a body tissue or organ, usually caused by a break or tear in a blood vessel.

HEMATOPOIESIS. The process of blood cell formation from stem cells in the medulla of the bone (bone marrow).

HEMATURIA. The presence of blood in the urine.

HEME. The iron-containing molecule in hemoglobin that serves as the site for oxygen binding. Each of the four hemoglobin chains has one heme molecule.

HEMI. One-sided.

HEMIHYPERPLASIA. A condition in which overdevelopment or excessive growth of one-half of a specific organ or body part on only one side of the body occurs.

HEMIPLEGIA. Paralysis of one side of the body.

HEMIVERTEBRA. A defect in which one side or half of a vertebra fails to form.

HEMIZYGOUS. Having only one copy of a gene or chromosome.

HEMOCHROMATOSIS. A condition in which iron accumulates in the body, as a result of either a genetic mutation or frequent blood transfusions. It is also known as iron storage disease.

HEMOCHROMATOSIS. Accumulation of large amounts of iron in the tissues of the body.

HEMOGLOBIN. A protein-iron compound in the blood that carries oxygen to the cells and carries carbon dioxide away from the cells.

HEMOGLOBIN A (HBA). Normal adult hemoglobin; it consists of two alpha globins and two beta globins.

HEMOGLOBIN A1C (HBA1C). A blood test that indicates average blood glucose levels over the previous two or three months.

HEMOGLOBIN E. An abnormal hemoglobin with a single-point mutation in the beta chain. People who inherit the hemoglobin E gene from one parent and the beta thalassemia gene from the other develop hemoglobin E beta thalassemia, which is a severe disease.

HEMOGLOBIN ELECTROPHORESIS. A laboratory test that separates molecules based on their size, shape, or electrical charge.

HEMOGLOBIN F (HbF). Fetal hemoglobin; it consists of two alpha and two gamma globins. HbF is produced by the fetus in utero and until about 48 weeks after birth. At this stage, the production of HbA rapidly increases while that of HbF drops off.

HEMOGLOBIN S. The most common type of abnormal hemoglobin; it is the basis of sickle cell trait and sickle cell anemia.

HEMOLYTIC. Refers to the type of anemia caused by the breakdown of red blood cells, as compared to anemia due to decreased production, for example.

HEMOLYTIC ANEMIA. Anemia that results from premature destruction and decreased numbers of red blood cells.

HEMORRHAGE. Very severe, massive bleeding that is difficult to control. Hemorrhage can occur in people with hemophilia after what would be relatively minor injuries for persons with normal clotting factors.

HEMOSIDERIN. An iron storage complex found only within cells (not in blood plasma) and consisting of ferritin, denatured ferritin, and other materials.

HEMOSTASIS. The arrest of bleeding by blood coagulation.

HEPATECTOMY. The medical term for surgical removal of the liver. A hepatectomy may be either partial or total.

HEPATIC. Pertaining to the liver.

HEPATITIS. A viral disease characterized by inflammation of the liver cells (hepatocytes). People who are infected with hepatitis B or hepatitis C virus are at an increased risk for developing liver cancer.

HEPATOMEGALY. Abnormal enlargement of the liver.

HEPATOSPLENOMEGALY. Abnormal enlargement of the liver and spleen.

HER2. Human epidermal growth factor receptor 2 (EGFR2); also called HER2/neu or erbB-2; a protein overproduced in HER2-positive cancers.

HEREDITARY. The passing of traits from parents to their offspring.

HEREDITARY ANGIONEUROTIC EDEMA. Abbreviated HANE, or HAE, this is an inherited kind of angioneurotic edema. Type I HANE is caused by a deficiency of C1-INH. Type II HANE is caused by a malformation of the C1-INH protein.

HEREDITARY NONPOLYPOSIS COLORECTAL CANCER (HNPCC). Lynch syndrome; the most common familial cancer syndrome that increases the risk of colorectal cancer; caused by inherited mutations in any of several genes, most of which are involved in DNA repair.

HERMANSKY-PUDLAK SYNDROME (HPS). A rare form of albinism that can include other problems, such as blood clotting, and lung and bowel disorders; there are four types of HPS caused by defects in four different genes.

HERNIA. A rupture in the wall of a body cavity, through which an organ may protrude.

HERNIATION. The abnormal protrusion of an organ or other structure through a defect or natural opening in a membrane, muscle, bone, or other tissue.

HERTZ (HZ). A measurement of sound frequency; 1 Hz equals one cycle per second.

HETEROCHROMIA IRIDES. A medical term for individuals with different-colored eyes.

HETEROGENEOUS. A set of symptoms or a disorder caused by several different gene mutations.

HETEROGENEOUS TRAIT. A trait that is caused by both genetic and nongenetic factors.

HETEROPLASMY. The presence of two or more sources of mitochondrial DNA within a cell, person, or mitochondrion. It is an important factor in determining the likelihood or severity of a mitochondrial disease.

HETEROTAXY. A condition in which the thoracic and abdominal viscera are arranged abnormally across the left-right axis of the body. It is also referred to as heterotaxy syndrome or visceral heterotaxy.

HETEROTOPIA. Small nodules of gray matter that are present outside the cortex.

HETEROZYGOTE. Having two different versions of the same gene.

HETEROZYGOUS. Referring to the genetic condition of having inherited two different forms (alleles) of a particular gene from each of a person's two parents.

HETEROZYGOUS MUTATION. A mutation in which both copies of a gene are mutated.

HIATAL HERNIA. A structural defect in the digestive tract in which the upper part of the stomach protrudes (herniates) through an opening or weak area in the diaphragm into the chest.

HIGH-DENSITY LIPOPROTEIN (HDL). A cholesterol carrying substance that helps remove cholesterol from the cells of the body and deliver it to the liver where it is digested and removed from the body.

HIGHLY AEROBIC TISSUES. Tissue that requires the greatest amount of oxygen to thrive.

HIPPOCAMPUS. A part of the brain that is involved in learning and memory formation.

HIRSCHSPRUNG DISEASE. A deformation in which the colon becomes enlarged (megacolon) due to abnormal nerve control of that portion of the large intestine.

HIRSUTISM. The presence of coarse hair on the face, chest, upper back, or abdomen in a female as a result of excessive androgen production.

HISTAMINE. A substance released by immune system cells in response to the presence of an allergen. Histamine stimulates widening of blood vessels and increased porousness of blood vessel walls so that fluid and protein leak out from the blood to surrounding tissue, causing inflammation.

HISTOCOMPATIBILITY. The degree to which two people's genetically determined human leucocyte antigen (HLA) alleles (tissue types) match. The higher the level of histocompatibility, the greater the likelihood of successful organ transplantation.

HISTOLOGIC. Pertaining to histology, the study of cells and tissues at the microscopic level.

HISTOLOGICAL STUDIES. Laboratory tests performed on tissue samples and cells.

HISTONE ACETYLATION. The addition of an acetyl group, a three-carbon molecule, at one end of a histone molecule. This DNA acetylation alters gene function without changing any DNA base pairings.

HISTONES. Alkaline proteins found in cell nuclei that act as spools for winding strands of DNA, allowing the DNA to be stored compactly within the cell nucleus.

HITCHHIKER THUMBS. A congenital anomaly of the thumb in which it is abnormally positioned at a right angle to the first joint.

HLA TYPE. The unique set of proteins called human leukocyte antigens. These proteins are present on each individual's cells. They allow the immune system to recognize 'self' from 'non-self'. HLA type is particularly important in organ and tissue transplantation.

HLA-B27. Stands for a specific form of human leukocyte antigen, the proteins involved in immune system function. Strongly associated with ankylosing spondylitis.

HOLOPROSENCEPHALY. A malformation of the brain in which the two hemispheres or lobes of the brain do not separate properly.

HOLT-ORAM SYNDROME. An inherited disorder characterized by congenital heart defects and abnormalities of the arms and hands; may be associated with Duane retraction syndrome.

HOMEOSTASIS. A state of physiological balance.

HOMEOTIC GENES. Developmental control genes active in the embryo.

HOMOCYSTEINE. An amino acid that is not used to produce proteins in the human body.

HOMOGENTISATE 1,2-DIOXYGENASE (HGD). Homogentisic acid oxidase, the fourth enzyme in the metabolic pathway for the breakdown of phenylalanine.

HOMOGENTISIC ACID (HGA). 2,5-Dihydroxyphenylacetic acid, the third intermediate in the metabolic pathway for the breakdown of phenylalanine.

HOMOLOGOUS. Similar in relation, position, value, or structure.

HOMOLOGOUS CHROMOSOMES. The two members of a chromosome pair, one inherited from each parent.

HOMOPLASMY. When all copies of mitochondrial DNA are the same, or have the same mutation.

HOMOZYGOUS. Having two identical copies of a gene or chromosome.

HORMONE. A chemical messenger produced by the body that regulates specific bodily functions such as growth, development, and reproduction.

HORMONE THERAPY. Treatment of cancer by changing the hormonal environment, such as testosterone and estrogen.

HOST. The body that a virus has infected.

HRAS. The gene encoding the H-Ras protein that helps regulate cell growth and division; mutations in *HRAS* can cause Costello syndrome.

HUMAN CHORIONIC GONADOTROPIN (HCG). A protein produced in early pregnancy; fetal chromosomal abnormalities can significantly increase hCG levels in maternal blood.

HUMAN GENOME PROJECT (HGP). An international collaboration begun in 1990 and completed in 2003 that sequenced the entire DNA sequence of the human genome.

HUMAN LEUKOCYTE ANTIGENS (HLAS). Proteins that form the major histocompatibility complex (MHC); some common HLA alleles are associated with the development of type 1 diabetes.

HUMORAL IMMUNITY. A type of acquired immunity mediated by B-cells and their secreted antibodies; important in fighting bacterial and some viral infections.

HUNTINGTON'S DISEASE. A hereditary disease that typically appears in midlife, marked by gradual loss of brain function and voluntary movement; some symptoms resemble those of schizophrenia. Also called Huntington's chorea.

HYALINE. A clear substance that occurs in cell deterioration.

HYDRANENCEPHALY. Congenital enlargement of the head and brain.

HYDROCEPHALUS. The excess accumulation of cerebrospinal fluid around the brain that often causes enlargement of the head.

HYDROLASE. An enzyme that uses water to break down substances.

HYDROLYSIS. The breakdown of chemical bonds by the addition of water.

HYDROMETROCOLPOS. An abnormal accumulation of fluids in the uterus and vagina.

HYDRONEPHROSIS. Obstruction of the tube that carries urine from the kidney into the bladder causing the pelvis and kidney duct to become swollen with excess urine.

HYDROPS FETALIS. A condition in which excess fluid builds up in a fetus's body prior to birth.

HYDROXYAPATITE. A complex phosphate of calcium $\text{Ca}_5(\text{PO}_4)_3\text{OH}$ that occurs as a mineral and is the chief structural element of vertebrate bone.

HYDROXYUREA. A drug that has been shown to induce production of fetal hemoglobin. Fetal hemoglobin has a pair of gamma-globin molecules in place of the typical beta-globins of adult hemoglobin. Higher-than-normal levels of fetal hemoglobin can prevent sickling from occurring.

HYGROMA. A condition in which fluid builds up in a sac or cyst.

HYPERAMMONEMIA. An excess of ammonia in the blood.

HYPERAROUSAL. Symptoms of traumatic stress characterized by abnormally intense reactions, such as a heightened startle response.

HYPERCALCEMIA. High levels of calcium in the blood.

HYPERCALCIURIA. Abnormally high levels of calcium in the urine.

HYPEREXCITABILITY. The abnormally intense response of muscle fiber membranes to stimulation.

HYPEREXTENSIBILITY. The ability to extend a joint beyond the normal range.

HYPEREXTENSION. The movement or extension of joints, bones, or muscles beyond the normal range of motion.

HYPERGLYCEMIA. High blood sugar.

HYPERHIDROSIS. Excessive perspiration that may be either general or localized to a specific area.

HYPERHOMOCYSTEINEMIA. Increased levels of homocysteine in the blood.

HYPERKERATOSIS. Abnormal thickening of the outermost layer of the skin, the stratum corneum.

HYPERLIPOPROTEINEMIA. An increase in the amount of lipoproteins in the body.

HYPERLORDOSIS. An exaggerated curve in the lower (lumbar) portion of the back.

HYPERMOBILITY. Unusual flexibility of the joints, allowing them to be bent or moved beyond their normal range of motion.

HYPEROSTOSIS. Overgrowth of the bone.

HYPERPHAGIA. Overeating.

HYPERPIGMENTATION. An abnormal condition characterized by an excess of melanin in localized areas of the skin, which produces areas that are much darker than the surrounding unaffected skin.

HYPERPLASIA. An overgrowth of normal cells within an organ or tissue.

HYPERREFLEXIA. Having overactive or overresponsive reflexes.

HYPERSENSITIVE. Referring to a process or reaction that occurs at above-normal levels; over-reacting to a stimulus.

HYPERSENSITIVITY. A process or reaction that occurs at above normal levels; overreaction to a stimulus.

HYPERTELORISM. A birth defect in which the child's eyes are spaced abnormally far apart.

HYPERTENSION. High blood pressure.

HYPERTHERMIA. Body temperature that is much higher than normal (above 98.6°F, 37°C).

HYPERTONIA. Excessive muscle tone or tension, causing resistance of muscle to being stretched.

HYPERTRICHOSIS. Excessive hair growth; also called hirsutism.

HYPERTROPHY. Increase in the size of a tissue or organ brought on by the enlargement of its cells rather than cell multiplication.

HYPNAGOGIC HALLUCINATIONS. Dream-like auditory or visual hallucinations that occur while falling asleep.

HYPOALBUMINEMIA. An abnormally low level of albumin in the blood.

HYPOCHONDROGENESIS. A condition similar to Langer-Saldino achondrogenesis caused by different mutations in the *COL2A1* gene.

HYPOCHONDROPLASIA. An autosomal dominant form of dwarfism where physical features are similar but milder than those of achondroplasia. Affected individuals have mild short stature and a normal facial appearance.

HYPOCRETIN. A neuro-hormone involved in the regulation of sleep, wakefulness, and eating behaviors, also known as orexin.

HYPOGENITALISM. Incomplete or hindered development of the external reproductive organs.

HYPOGLYCEMIA. An abnormally low glucose (blood sugar) concentration in the blood.

HYPOGONADISM. Small testes in men and scarce or irregular menstruation for females.

HYPOGONADOTROPIC HYPOGONADISM (HH). Underdevelopment of the gonads due to a deficiency of gonadotropin-releasing hormone.

HYPOHIDROSIS. Insufficient perspiration or absent perspiration that may be either general or localized to a specific area.

HYPOKETOSIS. Decreased levels of ketone bodies.

HYPOMELANOTIC MACULES. Patches of skin lighter than the surrounding skin.

HYPOMYELINATION. The death of myelin on a nerve or nerves.

HYPOPHOSPHATEMIA. A decrease in the blood circulation of phosphate.

HYPOPIGMENTATION. Decreased or absent color (pigment) in a tissue.

HYPOPLASIA. Incomplete or underdeveloped tissue or organ.

HYPOPLASTIC RADIUS. Underdevelopment of the radius, the outer, shorter bone of the forearm.

HYOSPADIAS. A birth defect in which the opening to the urinary tract, called the urethra, is located away from the tip of the penis.

HYPOTHALAMUS. A part of the forebrain that controls heartbeat, body temperature, thirst, hunger, body temperature and pressure, blood sugar levels, and other functions.

HYPOTHYROID. Deficiency in thyroid gland activity or thyroid hormone levels.

HYPOTHYROIDISM. A condition in which the patient's thyroid gland does not produce enough thyroid hormone.

HYPOTONIA. A state of low muscle tone that often involves loss of muscle strength as well. Infants with hypotonia are often described as having "floppy baby syndrome"; they may have difficulty lifting their heads and usually have problems with feeding.

IATROGENIC. Referring to a symptom or disorder caused inadvertently by a medical intervention or diagnostic procedure.

ICHTHYOSIS. A skin condition characterized by a fish-scale appearance.

IDIOPATHIC. Referring to a disease of unknown origin or arising spontaneously.

IGE. An antibody composed of protein; specific forms of IgE produced by cells of the immune system in response to different antigens that contact the body; a major factor that stimulates the allergic response.

ILIAC ARTERIES. Arteries that supply blood to the lower body including the pelvis and legs.

IMMUNE RESPONSE. Defense mechanism of the body provided by its immune system in response to the presence of an antigen, such as the production of antibodies.

IMMUNE SYSTEM. The complex group of organs and cells that defends the body against infection and disease.

IMMUNODEFICIENCY. A defect in the immune system, leaving an individual vulnerable to infection.

IMMUNOGLOBULIN. A protein molecule formed by mature B cells in response to foreign proteins in the body; the building blocks for antibodies.

IMMUNOLOGIC. Related to immunology, the study of how the body's immune system fights disease. Many immunologic disorders are characterized by the body's use of antibodies.

IMMUNOTHERAPY. A form of treatment that uses biologic agents to enhance or stimulate normal immune function.

IMPERFORATE ANUS. Also known as anal atresia. A birth defect in which the opening of the anus is absent or obstructed.

IMPOTENCE. The inability to have a penile erection, which can be due to tissue damage resulting from sickling within the penis (priapism).

IMPRINTING. A process that silences a gene or group of genes. The genes are silenced depending on whether they are inherited through the egg or the sperm.

INBORN ERROR OF METABOLISM. Any of a number of rare genetic disorders that inhibit the body's ability to turn food into energy.

INCLUSION BODY. An abnormal storage compartment inside a cell.

INCOMPLETE PENETRANCE. Absence of disease in an individual known to carry the gene for that disease.

INDIRECT COOMBS TEST. A test given to pregnant women to detect the presence of circulating antibodies against red blood cells.

INDUCED PLURIPOTENT STEM CELLS. Adult stem cells whose genes have been changed so that they act like embryonic stem cells. They can make copies of themselves indefinitely and can develop into many types of cell.

INDUCTION. Process where one tissue (the prechordal plate, for example) changes another tissue (for example, changes tissue into neural tissue).

INFANTILE SPASMS. The form of grand mal or focal seizures experienced by infants prior to the development of many voluntary muscular controls.

INFECTIVE ENDOCARDITIS. An infection of the tissue lining the walls of the heart.

INFERIOR OLIVARY NUCLEUS. A small collection of cells seen in the lower part of the brain stem, which has connections to the cerebellum and is involved in control of movements.

INFERTILE. Incapable of reproduction.

INFLAMMATION. An immune-system response, usually resulting from irritation, infection, or injury and causing redness, swelling, and pain.

INFORMED CONSENT. The process in which health-care professionals explain the purpose, risks, benefits, and alternatives of a proposed test or treatment to a patient, and make sure that the patient understands the explanation.

INGUINAL HERNIA. A condition in which part of the intestines protrudes through a tear in the muscles of the abdomen.

INHERITED GIANT PLATELET DISORDER (IGPD). A group of hereditary conditions that cause abnormal blood clotting and other conditions.

INNATE IMMUNE SYSTEM. A population of cells and mechanisms that defends the body against invasive

organisms. This protection is generic and not long lasting. The innate immune system is sometimes considered to be the first responder against infection.

INSEMINATION. The process by which sperm is placed into the female reproductive tract for the purpose of impregnation.

INSERTION. A mutation in which part of a chromosome is deleted from its normal location and implanted into another chromosome.

INSOMNIA. An inability to either fall or stay asleep, particularly at a time of day when sleep is expected. A number of medications are available, and may be used, for treatment.

INSULIN. A hormone encoded by the *INS* gene that is required for the metabolism of carbohydrates, fats, and proteins and that regulates blood sugar levels; lack of insulin or insulin insensitivity results in high blood sugar levels and diabetes.

INSULIN-LIKE GROWTH FACTOR I. A hormone released by the liver in response to high levels of growth hormone in the blood. This growth factor is very similar to insulin in chemical composition, and like insulin, it is able to bring about cell growth by causing cells to undergo mitosis (cell division).

INSULIN RECEPTOR GENE. The gene responsible for the production of insulin receptor sites on cell surfaces. Without properly functioning insulin receptor sites, cells cannot attach insulin from the blood for cellular use.

INSULIN RESISTANCE. An inability to respond normally to insulin in the bloodstream.

INTEGRATED SCREENING. Blood tests and ultrasound in the first trimester, followed by blood tests for three or four proteins in the second trimester, to screen for chromosomal abnormalities and neural tube defects.

INTELLECTUAL DISABILITY. Significant impairment in intellectual function and adaptation in society. Usually associated with an intelligence quotient (IQ) below 70.

INTERFERON. Any of a group of cells signaling proteins that are made and released by cells in response to the presence of viruses, bacteria, and other disease organisms. The name is derived from the way in which these proteins interfere with the replication of viruses by protecting cells from virus infections.

INTERPERSONAL THERAPIES. This type of psychological counseling focuses on determining how dysfunctional interpersonal relationships of the affected individual may be causing or influencing symptoms of depression.

INTERSTITIAL DELETION. The deletion of a piece of one chromosome.

INTRACRANIAL HEMORRHAGE. Abnormal bleeding within the space of the skull and brain.

INTRACRANIAL PRESSURE. The pressure of the fluid between the brain and skull.

INTRACYTOPLASMIC SPERM INJECTION (ICSI). In vitro fertilization in which sperm is injected directly into the cytoplasm of the egg.

INTRAGENIC. Occurring within a single gene.

INTRAGENOMIC. Pertaining to components of one genome.

INTRAUTERINE. Of, situated in, used in, or occurring within the uterus.

INTRAUTERINE GROWTH RETARDATION (IUGR). The slow or poor growth of a fetus during the mother's pregnancy. It can be caused by malnutrition or lack of an adequate oxygen supply to the fetus, as well as by genetic disorders.

INTRAVENOUS. A route for administration of fluids, nutrients, blood products, or medications. A small flexible plastic tube is inserted into a vein by way of a needle to establish this route.

INTRAVENOUS PYELOGRAM. An x-ray assessment of kidney function.

INTRON. A portion of the DNA sequence of a gene that is not directly involved in the formation of the chemical that the gene codes for.

INTUSSUSCEPTION. One piece of bowel inside another, causing obstruction.

IN UTERO. While in the uterus; before birth.

INVERSION. A rearrangement of genetic material within a chromosome that occurs when a portion of the chromosome breaks off, is reversed end to end, and is reattached.

IN VITRO FERTILIZATION (IVF). A form of assisted reproduction technology in which a human ovum (egg) is combined with sperm outside the body in a laboratory container ("in vitro" means "in a glass").

IN VIVO. The gene therapy is done directly on cells that are inside of the body.

ION CHANNEL. A transmembrane protein that transports ions across a plasma membrane in the direction of their concentration (electrochemical) gradient; also called ion pump. Also called an ion transporter.

IONIZING RADIATION. High-energy radiation such as that produced by x-rays.

IPSILATERAL. Situated or appearing on or affecting the same side of the body.

IRIS. The colored ring between the cornea and lens of the eye that controls the amount of light entering through the pupil.

IRON DEFICIENCY ANEMIA. A decrease in the number of red cells in the blood caused by too little iron in the diet, poor absorption of iron by the body, or loss of blood.

IRON OVERLOAD. A side effect of frequent blood transfusions in which the body accumulates abnormally high levels of iron. Iron deposits can form in organs, particularly the heart, and cause life-threatening damage.

ISCHEMIC ATTACK. A period of decreased or no blood flow.

ISCHIOPAGUS. Conjoined twins who are attached at the lower half of the body.

ISOCHROMOSOME. A chromosome is normally composed of two sections referred to as p and q; instead, an isochromosome is an abnormal chromosome made up of two p sections or two q sections.

ISOMERISM. In human anatomy, a condition in which organs normally found on only one side of the body are found on both sides. In reference to the heart, isomerism refers to a condition in which the heart has either two right sides with two right atria or two left sides with two left atria.

ISOTOPE. Any of two or more species of atoms of a chemical element with the same atomic number and nearly identical chemical behavior but with differing atomic mass and physical properties.

ISOZYME/ISOENZYME. A group of enzymes that perform the same function, but are different from one another in their structure or how they move.

IVEMARK SYNDROME. A rare disorder characterized by cardiovascular anomalies as well as asplenia or hypoplasia of the spleen. It is named for Biörn Ivemark (1925–2005), the Swedish pediatrician who first identified the syndrome in 1955.

J

JAUNDICE. Yellowing of the skin or eyes due to excess of bilirubin in the blood.

JOINT CONTRACTURE. Inability of the limbs to fully extend.

JOINT DISLOCATION. The displacement of a bone from its socket or normal position.

K

KABUKI. Traditional Japanese popular drama performed with highly stylized singing and dancing using special makeup and cultural clothing.

KALLIKREIN. A protein necessary for the activation of chemicals that cause dilation of blood vessels to allow increased blood flow to an area that requires more blood than normal. It is also capable of cleaving the complement, C5, into C5a, a much more robust and active form of this complement molecule.

KANNER'S SYNDROME. Another name for autism.

KARYOTYPE. A standard arrangement of photographic or computer-generated images of chromosome pairs from a cell in ascending numerical order, from largest to smallest.

KARYOTYPING. A laboratory procedure in which chromosomes are separated from cells, stained, and arranged so that their structure can be studied under a microscope.

KERATIN. A tough, non-water-soluble protein found in the nails, hair, and outermost layer of skin. Human hair is made up largely of keratin.

KERATINIZATION. The conversion of the epidermis into the stratum corneum.

KERATINOCYTES. Skin cells.

KERATOACANTHOMA. A firm nodule on the skin typically found in areas of sun exposure.

KERATOLYTIC. An agent that dissolves or breaks down the outer layer of skin (keratins).

KERATOSIS. A raised thickening of the outer horny layer of the skin.

KETOACIDOSIS. A condition that results when organic compounds (such as propionic acid, ketones, and fatty acids) build up in the blood and urine.

KETOGENIC DIET. A high-fat, low-carbohydrate diet used to treat epilepsy in children who do not respond to anticonvulsant medications.

KETOLACTIC ACIDOSIS. The overproduction of ketones and lactic acid.

KETONE BODIES. Products of fatty acid metabolism in the liver that can be used by the brain and muscles as an energy source.

KETONURIA. The presence of excess ketone bodies (organic carbohydrate-related compounds) in the urine.

KETOSIS. An abnormal build-up of compounds called ketones in the blood. This condition usually indicates a problem with blood sugar regulation.

KIDNEY STONES. Mineral deposits that form inside the kidney.

KIDNEY TUBULES. A portion of the kidneys that causes water to be excreted as urine or reabsorbed into the body.

KIDNEYS. The two organs in the lumbar region that filter the blood, excreting the end products of the body's metabolism in the form of urine, and regulating the concentrations of hydrogen, sodium, potassium, phosphate, and other ions in the body.

KLINEFELTER SYNDROME. A genetic disorder characterized by one or more extra X chromosomes in a male, with a 47,XXY, 48,XXXY, or 49,XXXXY karyotype. Most men with this syndrome are infertile or have reduced fertility. The syndrome is named for Harry Klinefelter (1912–1990), an American endocrinologist who first described it in 1942.

KNOBLOCH SYNDROME. A rare genetic disorder characterized by cataracts in the eye, degeneration and detachment of the retina, and occipital encephalocele.

KNOCK-IN. Referring to an organism that has been genetically engineered to alter a specific genetic locus by a one-for-one substitution of DNA sequence information or by the addition of DNA sequence information that is not found on the genetic locus in question.

KNOCKOUT. Referring to an organism that has been genetically engineered to lack one or more specific genes.

KURU. An incurable neurodegenerative disease that is classified as a transmissible spongiform encephalopathy. It is transmitted among humans by cannibalism.

KYPHOSCOLIOSIS. Abnormal front-to-back and side-to-side curvature of the spine.

KYPHOSIS. Abnormal outward curvature of the spine resulting in a hunchback.

L

L1 SYNDROME. Inherited disorder that primarily affects the nervous system caused by mutations in the *LICAM* gene. L1 syndrome involves a variety of features including muscle stiffness (spasticity) of the lower limbs,

intellectual disability, hydrocephalus, and thumbs bent toward the palm (adducted thumbs).

LABIA. The two parts of the vulva (the external female genitalia).

LABORATORY, DATA ANALYSIS, AND COORDINATING CENTER (LDACC). The center designated for the coordination for the GTEx project, including sample processing and de-identification, database management, and eQTL analysis.

LACRIMAL DUCTS. Tear ducts.

LACTIC ACID. The major by-product of anaerobic (without oxygen) metabolism.

LACTIC ACIDOSIS. A condition characterized by the accumulation of lactic acid in bodily tissues. The cells of the body make lactic acid when they use sugar as energy. If too much of this acid is produced, the person starts feeling ill with symptoms such as stomach pain, vomiting, and rapid breathing.

LACTOSE. A sugar made up of glucose and galactose. It is the primary sugar in milk.

LAMININ. A protein in connective tissue that is important for cell adhesion.

LAMININ, BETA-2. A protein involved in various biological processes that include cell migration, adhesion, and the formation of basement membranes in the kidneys and the smooth muscle lining of arteries and veins. Mutations in the gene that encode this protein are responsible for Pierson syndrome.

LAPAROSCOPIC. Visual examination of the abdomen by means of a laparoscope.

LAPAROSCOPY. A diagnostic procedure in which a small incision is made in the abdomen and a slender, hollow, lighted instrument is passed through it. The doctor can view the ovaries more closely through the laparoscope and, if necessary, obtain tissue samples for biopsy.

LAPAROTOMY. An operation in which the abdominal cavity is opened up.

LARYNX. The voice box, or the organ that contains the vocal cords.

LASER ABLATION. Removal of a skin papula with a laser beam.

LASER-ASSISTED IN-SITU KERATOMILEUSIS (LASIK). A surgical procedure that uses a cutting tool and a laser to modify the cornea and correct moderate to high levels of myopia.

LASER-ASSISTED SUB-EPITHELIAL KERATOMILEUSIS (LASEK). A surgical procedure in which the epithelium is loosened on the corneal surface. The loosened epithelium is then reflected away from the cornea, and laser ablation performed.

LATE-ONSET AD. Alzheimer's disease that develops after age 65.

LATENCY. The ability of some viruses to remain dormant in the body after the acute infection has subsided.

LATERAL RECTUS MUSCLE. The muscle that turns the eye outward toward the ear (abduction).

LATERALITY. The right-left distribution of the internal organs.

L-CARNITINE. A substance made in the body that carries wastes from the body's cells into the urine.

LEADER SEQUENCE/LEADER RNA. Also known as the 5' untranslated region (5' UTR or five prime UTR), the section of mRNA found immediately before the initiation codon for translation of a transcript.

LEARNING DISABILITY. Refers generally to a group of disorders manifested by significant difficulties in the acquisition and use of listening, speaking, reading, writing, reasoning, or math abilities.

LEBER HEREDITARY OPTIC ATROPHY OR LEBER HEREDITARY OPTIC NEUROPATHY (LHON). Discovered in 1871 by Theodore Leber, the painless loss of central vision in both eyes, usually occurring in the second or third decade of life, caused by a mutation in mitochondrial DNA. Other neurological problems, such as tremors or loss of ankle reflexes, may also be present.

LEFT VENTRICLE. Portion of the heart from which blood is pumped into the system.

LEFT VENTRICULAR ENLARGEMENT. Abnormal enlargement of the left lower chamber of the heart.

LEFT-RIGHT AXIS. The developmental feature in a fetus that determines which side of the body is left and which side is right; it conducts the location and positioning of the fetus's internal organs.

LEIGH SYNDROME. A rare genetic disease associated with mutations in either mitochondrial DNA or nuclear DNA, and characterized by degeneration of the central nervous system. It is named for Archibald Denis Leigh, a British psychiatrist who first described the syndrome in 1951.

LEIOMYOMAS. Benign tumors in the smooth muscle tissue of the uterus. They are also known as fibroids.

LENS. The transparent, elastic, curved structure behind the iris (colored part of the eye) that helps to focus light on the retina.

LENTIGO (PLURAL, LENTIGINES). A dark colored spot on the skin.

LEPROSY. A chronic, contagious skin and nervous system disease that leads, in the more serious form, to numbness, muscle weakness, and paralysis. Leprosy is sometimes referred to as Hansen's disease.

LEPTOMENINGEAL ANGIOMA. A swelling of the tissue or membrane surrounding the brain and spinal cord, which can enlarge with time.

LESION. A defective or injured section or region of the brain (or other body organ).

LETHARGY. Fatigue.

LEUCOPENIA. A decrease in white blood cells.

LEUKEMIA. Cancer of the blood-forming organs, which results in an overproduction of white blood cells.

LEUKOCEPHALOPATHIES. Defects in the white matter of the brain.

LEUKOCORIA. An abnormal white reflection from the retina.

LEUKOCYTE. A white blood cell. The neutrophils are a type of leukocyte.

LEUKOCYTOSIS. An increase in the number of leukocytes in the blood.

LEUKODYSTROPHY. A disease that affects the white matter, called myelin, in the CNS.

LEUKOENCEPHALOPATHY. Any of various diseases, including leukodystrophies, affecting the brain's white matter.

LEVODOPA. A chemical produced naturally in the body that is a precursor to such neurotransmitters as serotonin and epinephrine. It is also manufactured as a drug and used to treat Parkinson's disease and the dopa-responsive dystonias.

LEVOTHYROXINE. A form of thyroxine (T4) for replacement of thyroid hormones in hypothyroidism.

LEWY BODY DEMENTIA (LBD). A common progressive form of dementia in which protein aggregates called Lewy bodies form in neurons.

LHERMITTE-DUCLOS DISEASE. A rare form of benign brain tumor.

LIFETIME RISK. A risk that exists over a person's lifetime; a lifetime risk to develop disease means that the chance is present until the time of death.

LI-FRAUMENI SYNDROME. A rare familial cancer syndrome characterized by high risk for early-onset breast cancer and soft-tissue sarcomas.

LIGAMENT. A type of connective tissue that connects bones or cartilage and provides support and strength to joints.

LIGHT CHAINS. The two small polypeptide chains found in an immunoglobulin (antibody) molecule. The other two components of the antibody are so-called heavy chains.

LIMB GIRDLES. The areas of the body around the shoulders and hips.

LIMITED SCLERODERMA. A subtype of systemic scleroderma with limited skin involvement. It is sometimes called the CREST form of scleroderma, after the initials of its five major symptoms.

LINCOLN ATAXIA (SCA5). Spinocerebellar ataxia type 5; an adult-onset cerebellar ataxia caused by autosomal dominant mutations in the SPTBN2 gene.

LINKAGE. The association between separate DNA sequences (genes) located on the same chromosome.

LINKAGE ANALYSIS. A method of finding mutations based on their proximity to previously identified genetic landmarks.

LIPASE. A digestive enzyme found in pancreatic fluid that breaks down fats.

LIPIDS. A class of organic compounds defined by their tendency to dissolve in organic liquids, such as alcohol and ether, but not in water.

LIPODYSTROPHY. A medical condition characterized by abnormal or degenerative conditions of the body's adipose tissue.

LIPOFUSCIN. Pigment granules that are produced from lysosomal degradation. Lipofuscin normally accumulates over time and with age.

LIPOMA. A benign tumor composed of well-differentiated fat cells.

LIPOPIGMENTS. Substances made up of fats and proteins that can accumulate in different tissues of the body. They have a yellowish color to them under UV light. Lipopigments can result from oxidation of fatty acids and may be symptomatic of damage or aging.

LIPOPROTEIN. A complex molecule consisting of a lipid molecule joined with one or more protein molecules.

LIQUID BIOPSY. An informal term used to describe the use of cell-free tumor DNA in identifying the presence of cancer, staging it, evaluating its risk of metastasis, and monitoring the effects of treatment on the cancer's progression.

LISSENCEPHALY. A condition in which the brain has a smooth appearance because the normal convolutions (gyri) failed to develop.

LITHOTRIPSY. A procedure for treating kidney stones that involves the use of external shockwaves to break down the stones into small pieces that can be passed in the patient's urine.

LIVEDO RETICULARIS. Bluish net-like patterns of skin discoloration caused by blood-vessel abnormalities; usually present in children with recurrent fevers and strokes caused by *CECR1* gene mutations.

LOCALIZED SCLERODERMA. Thickening of the skin from overproduction of collagen.

LOCUS. Position occupied by a gene on a chromosome.

LONG BONES. The femur in the leg and the humerus in the arm.

LORDOSIS. An abnormal curvature of the spine in which the lumbar, or lower section, is excessively curved (also known as pigeon chest).

LOSS-OF-FUNCTION MUTATION. Any mutation that causes a gene to lose its ability to encode a protein, either partially or completely.

LOW-DENSITY LIPOPROTEINS (LDL). A cholesterol-carrying substance that can remain in the bloodstream for a long period of time.

LOWE SYNDROME. A rare X-linked recessive disorder characterized by congenital eye disorders as well as renal tubular dysfunction, and caused by mutations in the same gene as Dent disease 2.

LUMBAR LORDOSIS. Abnormal inward curvature of the spine.

LUPUS ERYTHEMATOSUS. A chronic inflammatory disease that affects many tissues and parts of the body including the skin.

LUTEINIZING HORMONE (LH). A hormone secreted by the pituitary gland that regulates the menstrual cycle and triggers ovulation in females. In males it stimulates the testes to produce testosterone.

LYMPH NODE. A bean-sized mass of tissue that is part of the immune system and is found in different areas of the body.

LYMPHANGIOMYOMATOSIS. Serious lung disease characterized by the overgrowth of an unusual type of muscle cell resulting in the blockage of air, blood, and lymph vessels to and from the lungs.

LYMPHATIC SYSTEM. Lymph nodes and lymphatic vessels that transport infection-fighting cells around the body.

LYMPHEDEMA DISTICHIASIS. A genetic syndrome caused by a mutation in the *FOXC2* gene on chromosome 16 and characterized by localized fluid retention and swelling of the limbs (lymphedema) and a double row of eyelashes (distichiasis).

LYMPHOCYTE. Any of three types of white blood cells that play an important role in the immune system. They include T cells, B cells, and natural killer (NK) cells.

LYMPHOMA. A general term for a group of cancers that affect the immune system; they develop from lymphocytes, cells in the lymphatic system.

LYMPHOPENIA. A condition marked by an abnormally low level of lymphocytes in the blood.

LYMPHOSCINTIGRAPHY. Procedure that helps to look at the lymph nodes in the body. Requires an injection of radioactive material to help see the lymph nodes and lymphatic system.

LYNCH SYNDROME. A genetic syndrome causing increased cancer risks, most notably colon cancer. Also called hereditary non-polyposis colon cancer (HNPCC).

LYSINE. A crystalline basic amino acid essential to nutrition.

LYSIS. Area of destruction.

LYSOSOMAL. Pertaining to the lysosomes, special parts (organelles) of cells that contain a number of enzymes important in the breakdown of large molecules such as proteins and fats.

LYSOSOMAL ACID LIPASE. An enzyme that catalyzes the hydrolytic breakdown of lipids in the lysosome. This enzyme is coded by the *LIPA* gene.

LYSOSOMAL STORAGE DISEASES. A group of more than 40 human genetic disorders that result from defects in lysosomal function.

LYSOSOME. A membrane-enclosed compartment in cells that contains many hydrolytic enzymes where large molecules and cellular components are broken down.

LYST. The gene that encodes the lysosomal trafficking regulator protein that is required for normal functioning of lysosomes and similar subcellular compartments.

M

MACHINE LEARNING. A subtype of artificial intelligence (AI) based on the concept that a computer can learn and adapt to new data inputs without human intervention. Applied to polygenic risk scoring, machine learning is said to improve the accuracy of PRS scores as the computer is given new population data without the need for a human operator to adjust the computer's algorithm.

MACROCEPHALY. Having an abnormally large head.

MACROGLOSSIA. Abnormal enlargement or thickening of the tongue.

MACROPHAGE. Specialized white blood cells that play a role in breaking down old or abnormal red blood cells.

MACROSOMIA. Overall large size due to overgrowth.

MACROTIA. Abnormally large ears.

MACROZOOSPERMIA. Macrocephalic sperm head syndrome; male infertility due to sperm with abnormally large heads and multiple (usually four) flagella; caused by mutations in the *AURKC* gene.

MACULA. A small spot located in the back of the eye that provides central vision and allows people to see colors and fine visual details.

MACULAR DEGENERATION. Progressive condition that affects the macula, a small portion of the retina at the back of the eye.

MACULE. A flat, discolored spot or patch on the skin.

MADAROSIS. The medical term for loss of hair from the eyebrows or eyelashes. Madarosis may be associated with a form of alopecia areata called alopecia totalis. It may also result from such diseases as leprosy and syphilis, or from trauma.

MADLUNG DEFORMITY. A forearm bone malformation characterized by a short forearm, an arced or bow-shaped radius, and dislocation of the ulna, resulting in wrist abnormalities.

MAFFUCCI DISEASE. A manifestation of Ollier disease (multiple enchondromatosis) with hemangiomas, which present as soft tissue masses.

MAGNETIC RESONANCE IMAGING (MRI). A diagnostic procedure that uses a combination of high powered

magnets, radio frequencies, and computers to generate detailed images of structures within the body.

MAJOR DEPRESSION. A psychological condition in which the patient experiences one or more disabling bouts of depression lasting two or more weeks.

MAJOR HISTOCOMPATIBILITY COMPLEX (MHC). Includes HLA, as well as other components of the immune system. Helps the immune system function, in part by helping it to distinguish "self" from "non-self."

MALAR HYPOPLASIA. Small or underdeveloped cheekbones.

MALFORMATION. An abnormality in an organ or body structure caused by a dysfunctional developmental process.

MALIGNANT. Referring to a tumor growth that spreads to another part of the body, usually cancerous.

MALIGNANT HYPERTHERMIA. A rare, potentially fatal condition triggered by exposure to certain inhalational anesthetics, in which the body's metabolism speeds up and overwhelms its ability to regulate body temperature.

MALINGERING. Exaggerating or faking the symptoms of a physical or psychiatric illness in order to avoid work, school, or military service; obtain fraudulent financial compensation; or attract sympathy or attention.

MALOCCLUSION. Misalignment or incorrect relation between the teeth in the upper and lower jaws as the jaws close.

MALROTATION. An abnormality that occurs during the normal rotation of an organ or organ system.

MAMMOGRAPHY. A procedure in which both breasts are compressed (or flattened) and exposed to low doses of x rays in order to visualize the inner breast tissue.

MANDIBLE. The lower jaw bone.

MANNOSE. A type of sugar that forms long chains in the body and is important in metabolism and the glycosylation of proteins.

MANOMETRY. A balloon study of internal anal sphincter pressure and relaxation.

MAO-B INHIBITORS. Inhibitors of the enzyme monoamine oxidase B. MAO-B helps break down dopamine; inhibiting it prolongs the action of dopamine in the brain. Selegiline is an MAO-B inhibitor.

MARFAN SYNDROME. A syndrome characterized by skeletal changes (arachnodactyly, long limbs, lax joints), ectopia lentis, and vascular defects.

MARFANOID. Term for a body type that is similar to that of people with Marfan syndrome. Characterized by tall, lean body with long arms and long fingers.

MASCULINIZATION. Development of excess body and facial hair, deepening of the voice, and increase in muscle bulk in a female due to a hormone disorder.

MASSETER SPASM. Stiffening of the jaw muscles. Often one of the first symptoms of malignant hyperthermia susceptibility that occurs after exposure to a trigger drug.

MATERNAL SERUM SCREENING. A blood test offered to pregnant women usually under the age of 35, which measures analytes in the mother's blood that are present only during pregnancy, to screen for Down syndrome, trisomy 18, and neural tube defects.

MATERNAL UNIPARENTAL DISOMY. A chromosome abnormality in which both chromosomes in a pair are inherited from one's mother.

MATERNALLY INHERITED DIABETES AND DEAFNESS (MIDD). A rare type of diabetes caused by a mitochondrial gene inherited from the mother.

MATURITY-ONSET DIABETES OF THE YOUNG (MODY). A rare form of diabetes inherited in an autosomal dominant fashion. It is similar to type 2 diabetes but develops before the age of 25.

MAXILLAE. The two facial bones that fuse to form the upper jaw and the roof of the mouth in humans.

MAY-HEGGLIN ANOMALY. A subgroup of the *MYH9*-related disorders characterized by the platelet disorder and inclusion bodies in the white blood cells.

MECKEL SYNDROME. A fatal genetic disorder characterized by occipital encephalocele as well as other central nervous system defects, large polycystic kidneys, and incompletely developed lungs.

MECONIUM. The first waste products to be discharged from the body in a newborn infant, usually greenish in color and consisting of mucus, bile, and so forth.

MEDIAL RECTUS MUSCLE. The muscle that turns the eye inward toward the nose (adduction).

MEDIATOR COACTIVATOR COMPLEX. A large protein complex that binds to super enhancers to activate genes.

MEDIUM-CHAIN ACYL-COA DEHYDROGENASE. Abbreviated MCAD, this is the enzyme responsible for the breakdown of medium chain fatty acids in humans. People affected with MCAD deficiency produce a form of MCAD that is not as efficient as the normal form of MCAD.

MEDIUM-CHAIN FATTY ACIDS. Fatty acids containing between 4 and 14 carbon atoms.

MEDULLA. In general, the central portion of a body organ; with regard to bone, the marrow that lies at the center of the long bones. The English word is derived from the Latin word for marrow.

MEDULLARY CAVITY. The marrow-filled cavity inside of a long bone (such as the femur).

MEDULLARY THYROID CANCER (MTC). A slowly growing tumor associated with MEN.

MEDULLOBLASTOMA. Tumor of the central nervous system derived from undifferentiated cells of the primitive medullary tube.

MEGA BASE PAIRS (MBP). A million base pairs.

MEGACOLON. Extreme swelling of the colon that is a rare but life-threatening complication of colitis.

MEGALENCEPHALY. Enlarged brain.

MEIOSIS. The process of cell division during the production of ova and sperm, in which the material in the chromosomes undergoes recombination (first-stage meiosis), and the chromosomes are reduced to a single set of 23 instead of the normal number of 23 pairs (second-stage meiosis).

MEIOTIC DRIVER. A gene that affects or modifies the processes that control meiosis.

MELANIN. A pigment produced by the body that gives color to the skin, hair, and eyes.

MELANOCYTE. A cell that can produce melanin.

MELANOCYTIC NEVUS. A nevus that contains pigmented skin cells called melanocytes. Melanocytic nevi are skin lesions that are also commonly described as moles.

MELANOMA. Cancer that develops in melanocytes, the pigmented skin cells.

MELANOSOMES. Granules of pigment within melanocytes that synthesize melanin.

MELATONIN. A sleep-inducing hormone secreted by the pineal gland.

MEMORY CELLS. B-cells whose antibodies recognized antigens from a previous infection; able to mount a quick, efficient response upon a second infection by the same organism.

MENARCHE. The medical term for the first menstrual period in girls, typically between the ages of 10 and 16. Pronounced MEH-nar-key.

MENDEL, GREGOR. Austrian monk who discovered the basic principles of heredity.

MENDELIAN DISEASE. A disease caused by a single mutated gene; also called a single-gene disease. These diseases are named for Gregor Mendel (1822–1884), an Austrian monk who discovered the basic principles of inheritance of single-gene traits through experimentation with plants in his garden.

MENDELIAN GENETICS. A set of parameters describing the traditional method of the transmission of genes from one generation to the next.

MENINGES. The two-layered membrane that covers the brain and spinal cord.

MENINGITIS. An infection of the covering of the brain and spinal cord.

MENOPAUSE. The transition in a woman's life whereby menstrual periods stop.

MENSTRUATION. Discharge of blood and fragments of the uterine wall from the vagina in a monthly cycle in the absence of pregnancy.

MENTAL STATUS EXAMINATION (MSE). An evaluation of the ability to communicate, follow instructions, recall information, and complete movement and coordination tasks, as well as emotional state and general sense of space and time.

MERMAID SYNDROME. Alternate name for sirenomelia, often used in older references. An extremely rare birth defect in which affected infants are born with a single lower extremity or with two legs that are fused together.

MESENTERY. Tissue that attaches the intestines to the abdominal wall.

MESODERM. The middle germ layer in the developing embryo, lying between the ectoderm and the endoderm. It gives rise to muscle, cartilage, bone, and the subcutaneous layer of the skin.

MESOMELIA. Shortness of the portion of arm connecting the elbow to the wrist or forearm.

MESOMELIC. The anatomical term used to describe the middle of a limb. The bones that constitute the middle of the arm are the radius and ulna, and mesomelic bones of the leg are the tibia and fibula.

MESONEPHRIC DUCT. Embryonic structure that in the male becomes the vas deferens, and in both sexes gives rise to the ureters leading to the kidney.

MESSENGER RNA (MRNA). The single-stranded RNA molecule that delivers genetic instructions from the nucleus of a cell to the ribosomes, where proteins are made.

METABOLIC ACIDOSIS. High acidity (low pH) in the body due to abnormal metabolism, excessive acid intake, or retention in the kidneys.

METABOLIC DISORDER. A disorder that affects the metabolism of the body.

METABOLIC MYOPATHIES. A broad group of muscle diseases whose cause is a metabolic disturbance of some type.

METABOLIC PATHWAY. A sequence of chemical reactions that lead from some precursor to a product, where the product of each step in the series is the starting material for the next step.

METABOLISM. The total combination of all of the chemical processes that occur within the cells and tissues of a living body.

METABOLIZED. When a drug is converted into one or more compounds.

METACARPAL. A hand bone extending from the wrist to a finger or thumb.

METACENTRIC. A centromere in the middle of the chromosome.

METACHRONOUS. Occurring at separate time intervals.

METAGENOME. Genetic material taken directly from an environment.

METANEPHRIC BUD. An embryological precursor to renal organs.

METAPHASE. A stage in the cycle of cell division in which the cell's genetic material condenses into chromosomes, which become visible and line up in the center of the dividing cell.

METAPHYSEAL FLARING. A characteristic found only by x-rays. If present, it means that the ends of the bone are wider than normal.

METAPHYSIS. The growth zone of the long bones located between the ends (epiphyses) and the shaft (diaphysis) of the bone.

METASTASIS. The spreading of cancer from the original site to other locations in the body.

METASTASIZE. To spread to another part of the body.

METASTATIC CANCER. A cancer that has spread to an organ or tissue from a primary cancer located elsewhere in the body.

METATARSAL. A foot bone extending from the ankle to a toe.

METHEMOGLOBINEMIA. A medical condition of the blood characterized by the presence of an altered form of hemoglobin, known as methemoglobin.

METHYL GROUPS. Groups of one carbon and three hydrogen atoms attached to DNA. The number of methyl groups attached to a section of a chromosome influences the level of gene activity (repression or activation).

METHYLATION. The process in which methyl groups are added to DNA. Methylation typically acts to suppress a gene's ability to code for proteins.

METHYLATION TESTING. DNA testing that detects whether a gene is active, or whether it is imprinted.

METHYLMALONIC ACID. An intermediate product formed when certain substances are metabolized.

MICROARRAY. A supporting material (usually glass or plastic) to which DNA fragments of known sequence are attached for the identification and sequencing of DNA samples.

MICROBE. A microorganism.

MICROBIOME. All of the microorganisms normally present in a given environment, such as the human body.

MICROBIOTA. Microscopic living organisms.

MICROCEPHALIC. Having an abnormally small head.

MICROCEPHALIC PRIMORDIAL DWARFISM SYNDROMES. A group of disorders characterized by profound growth delay and small head size.

MICROCEPHALY. A birth defect in which the brain and head are too small.

MICROCORNEA. Abnormal smallness of the cornea.

MICROCYTE. An abnormally small red blood cell.

MICROCYTIC, HYPOCHROMIC ANEMIA. An anemia marked by too little hemoglobin and small red blood cells.

MICRODELETION. A chromosome deletion that is too small to be detected by standard karyotyping methods. Microdeletions are typically 1 to 3 mega bases in length (1 to 3 million base pairs), whereas standard deletions are 5 mega bases or longer.

MICRODELETION SYNDROME. A group of signs and symptoms caused by the deletion of a very small amount of chromosomal material.

MICRODONTIA. Abnormally small teeth.

MICRODUPLICATION. The abnormal doubling of a small segment of a chromosome that is too small to be detected by standard karyotyping.

MICROGNATHIA. A term used to describe a small, underdeveloped lower jaw and chin.

MICROMELIA. The state of having extremely short limbs.

MICROPTHALMIA. Small or underdeveloped eyes.

MICROSATELLITE INSTABILITY (MSI). An abnormally high rate of change in repeated short sequences of DNA (microsatellites) that indicates impairment of DNA mismatch repair.

MICROSCOPIC COLITIS. A form of colitis that can only be diagnosed by examining tissue under a microscope.

MICROSOMIA. A general term for an abnormally small body or body part.

MICROSTOMIA. The medical term for an abnormally small mouth.

MICROSURGICAL EPIDIDYMAL SPERM ASPIRATION (MESA). A surgical sperm retrieval method where a small needle is inserted into the epididymis and a syringe attached by tubing to the needle is used to withdraw the sperm under the observation of a microscope.

MICROTIA. A birth defect in which the external ear is underdeveloped. The condition is called anotia if the outer ear is completely missing.

MIDFACIAL HYPOPLASIA. Subnormal growth of the central face.

MIDLINE. An imaginary line that divides the body into right and left parts.

MIDLINE DEFECTS. Defects involving organs along the center of the body such as the lips, penis, and corpus callosum.

MIDLINE ORGANS. Organs found along the center of the body such as the lips, penis, and corpus callosum.

MIGRAINE. A condition marked by severe headaches, often on one side of the head and accompanied by nausea, light and sound sensitivity, and other symptoms. Migraines are believed to involve the nerves and blood vessels of parts of the brain and head.

MINIATURIZATION. The process of shortening and thinning of the hair shafts that is found in androgenetic alopecia. It is caused by the effects of DHT on the hair follicle.

MINOXIDIL. A topical medication sold under the trade name Rogaine for the treatment of male pattern hair loss. It is applied to the scalp as a 2% or 5% solution.

MIOSIS. The medical term for constriction of the pupil of the eye.

MISCARRIAGE. Spontaneous pregnancy loss.

MISMATCH REPAIR. Repair of gene alterations due to mismatching.

MISSEGREGATION OF CHROMOSOMES. The faulty segregation of chromosomes into the appropriate daughter cells, in either mitosis (cell division) or meiosis (reproductive cell [sperm or egg] production).

MISSENSE. A portion of mRNA in which the coding is changed because of an abnormal change in the protein base sequence.

MITOCHONDRIA. Structures found in the cell (organelles) surrounded by two layers of membrane. Mitochondria turn energy from food into energy that powers the cell. They also help the cell produce heat and store calcium, and they help choose which damaged cells need to be destroyed.

MITOCHONDRIAL DISEASE. Any of several hundred inherited conditions caused by functional failure of the mitochondria within cells.

MITOCHONDRIAL DNA (MTDNA). The DNA (genetic material) found in the mitochondria. MtDNA contains the instructions for about 37 genes. These genes produce proteins that help the mitochondria function. MtDNA is only passed from the mother to her offspring.

MITOCHONDRIAL GENES. A group of 37 genes contained in the DNA of mitochondria (mDNA), the energy-producing organelles in cells. In humans, mDNA is inherited solely from the mother.

MITOCHONDRIAL GENOME. The DNA (genetic material) found in the mitochondria. The mitochondrial genome contains the instructions for about 37 genes. These genes produce proteins that help the mitochondria function. Mitochondrial DNA is only passed from the mother to her offspring.

MITOCHONDRIAL INHERITANCE. Inheritance associated with the mitochondrial genome, which is inherited almost exclusively from the mother.

MITOCHONDRIAL MUTATION. Variation in the mitochondrial DNA that can affect how well the mitochondria function.

MITOCHONDRIAL REPLACEMENT THERAPY (MRT). A technique to prevent or treat certain genetic diseases by

replacing the mitochondria in one or more cells. It is also called mitochondrial donation.

MITOSIS. A process that takes place in the nucleus of a dividing cell, involves typically a series of steps consisting of prophase, metaphase, anaphase, and telophase, and results in the formation of two new nuclei each having the same number of chromosomes as the parent nucleus.

MITRAL VALVE. The heart valve that lies between the left ventricle of the heart and the left atrium. It is also called the bicuspid valve because it has two leaves or flaps.

MITRAL VALVE PROLAPSE. A heart defect in which one of the valves of the heart (which normally controls blood flow) becomes floppy. Mitral valve prolapse may be detected as a heart murmur, but there are usually no symptoms.

MODEL ORGANISM. A nonhuman species (which may be a plant, animal, or bacterium) that is studied to yield understanding of particular biological events or processes in the expectation that discoveries made in the model organism can be applied to other species.

MOHS SURGERY. A form of microscopically controlled surgery that allows for the precise removal of cancerous tissue. It is commonly used to treat various types of skin cancer, particularly in areas of the body where preserving as much tissue as possible is essential. Mohs surgery is also known as micrographic surgery.

MOLECULAR ANALYSIS. Evaluation of molecules, tests that may identify single gene mutations.

MOLECULAR GENETIC TESTING (GENE TESTS). Medical test that examines single genes or short lengths of DNA to identify changes or mutations that cause genetic disorders.

MONOCLONAL ANTIBODY (MAB). A protein, produced in large quantities in a laboratory, designed to attack a specific target in the body.

MONOGENETIC DISORDER. A disorder or disease that is caused by a mutation or defect in one gene.

MONOGENIC DISEASE. Another term for a single-gene disorder.

MONOSOMY. Missing an entire copy of a chromosome or a piece of one copy of a chromosome.

MONOZYGOTIC. From one zygote, as in identical twins. The zygote is the first cell formed by the union of sperm and egg.

MORPHEA. The most common form of localized scleroderma.

MORPHOGENESIS. The normal developmental process of the body's structure and form.

MOSAIC. A term referring to a genetic situation in which an individual's cells do not have the exact same composition of chromosomes. In Down syndrome, this may mean that some of the individual's cells have a normal 46 chromosomes, while other cells have an abnormal 47 chromosomes.

MOSAIC RETINOBLASTOMA. A type of retinoblastoma where a variant in one copy of the *RBI* gene is found in only some cells of the body.

MOSAICISM. A genetic condition resulting from a mutation, crossing over, or nondisjunction of chromosomes during cell division, causing a variation in the number of chromosomes in the cells.

MOTOR NEURONS. Class of neurons that specifically control and stimulate voluntary muscles.

MOTOR SKILLS DISORDER. A disorder that affects motor coordination or its development and the control of particular groups of muscles that perform activities.

MOTOR UNITS. Functional connection with a single motor neuron and muscle.

MOTTLED RETINA. Changes in the retina of the eye causing a loss of visual acuity.

MRNA (MESSENGER RNA). The single-stranded RNA molecule that delivers genetic instructions from the nucleus of a cell to the ribosomes, where proteins are made.

MUCOCILIARY ESCALATOR. The coordinated action of tiny projections on the surfaces of cells lining the respiratory tract, which moves mucus up and out of the lungs.

MUCOLIPID. A lipid that accumulates in cells in mucopolipidosis disorders.

MUCOLIPIN-1. A protein in the cell membrane, probably a calcium ion channel, involved in recycling membrane lipids and deficient in mucopolipidosis IV.

MUCOLYTIC. An agent that dissolves or destroys mucin, the chief component of mucus.

MUCOPOLYSACCHARIDE. A complex molecule made of smaller sugar molecules strung together to form a chain. Found in mucous secretions and intercellular spaces.

MUCOSA. Mucus-secreting membrane lining all body cavities or passages that communicate with the exterior.

MUCUS MEMBRANE. Thin, mucus-covered layer of tissue that lines organs such as the intestinal tract.

MÜLLERIAN DUCTS. Two embryo structures that in the female develop into vagina, uterus, and oviducts, and in the male disappear except for the vestigial vagina masculina and the appendix testis.

MULTIFACTORIAL. Describes a disease that is the product of the interaction of multiple genetic and environmental factors.

MULTIFACTORIAL DISORDERS. A general term for polygenic disorders complicated by the effects of environmental factors. Multifactorial disorders do not have clear patterns of inheritance. They are sometimes called complex diseases or disorders. PCOS in women is a multifactorial disorder.

MULTIFACTORIAL INHERITANCE. A type of inheritance pattern in which many factors, both genetic and environmental, contribute to the cause.

MULTIFOCAL. A pathological term meaning that instead of finding one tumor in the tissue, multiple tumors are found.

MULTIFOCAL BREAST CANCER. Multiple primary cancers in the same breast.

MULTIPLE CARBOXYLASE DEFICIENCY. A type of propionic acidemia characterized by an inability to metabolize biotin.

MULTIPLE SCLEROSIS (MS). A progressive degeneration of nerve cells that causes episodes of muscle weakness, dizziness, and visual disturbances, followed by periods of remission.

MULTIPLEX ASSAY. A procedure that allows the testing of several gene samples simultaneously.

MUSCULAR DYSTROPHY. A group of inherited diseases characterized by progressive wasting of the muscles.

MUTAGEN. An environmental influence that causes changes in DNA.

MUTANT. A change in the genetic material that may alter a trait or characteristic of an individual or manifest as disease.

MUTATED GENE. A change of DNA sequence that causes a change of the function of the gene and a subsequent disease.

MUTATION. A change in the DNA sequence of a gene that may alter a trait or characteristic of an individual and can be transmitted to offspring. The change may manifest itself as a disease.

MUTATION RATE. How often a virus makes errors when copying itself.

MYDRIATICS. Medications given to induce dilation of the pupil, usually as part of an eye examination.

MYELIN. A fatty sheath surrounding nerves in the peripheral nervous system that helps them conduct impulses more quickly.

MYELINATION. Production and maintenance of the myelin sheath.

MYELODYSPLASTIC SYNDROME (MDS). A bone marrow disorder that can develop into aplastic anemia, requiring bone marrow or stem cell transplantation.

MYELOMENINGOCELE. A sac protruding through an abnormal opening in the spinal column.

MYOCARDIAL DISARRAY. A condition in which the cells in the heart muscle are aligned in a disorderly fashion rather than in parallel lines.

MYOCARDIUM. The medical term for the muscle of the heart.

MYOCLONIC EPILEPSY. Epilepsy characterized by sudden jerking or twitching in the arms, legs, or upper body.

MYOCLONUS. Twitching or spasms of a muscle or an interrelated group of muscles.

MYOFIBROBLAST. A fibroblast (cell that forms connective tissue) that has some of the characteristics of a smooth muscle cell.

MYOGLOBINURIA. The abnormal presence of myoglobin, a product of muscle disintegration, in the urine. Results in dark-colored urine.

MYOPATHY. Any abnormal condition or disease of the muscle.

MYOPIA. Nearsightedness. Difficulty seeing objects that are far away.

MYOSIN. The most common protein in muscle cells, which interacts with actin during muscle contraction to form actomyosin.

MYOSIN HEAVY CHAIN 9 (MYH9)-RELATED DISORDERS (MYH9-RD). A group of inherited macrothrombocytopenias caused by mutations in the *MYH9* gene that cause abnormal blood clotting and other symptoms.

MYOTONIA. Sustained contraction or delayed relaxation of a muscle following voluntary contraction of that muscle.

MYOTONIC DYSTROPHY. A form of muscular dystrophy, also known as Steinert's condition, characterized by delay in the ability to relax muscles after forceful

contraction and wasting of muscles, as well as other abnormalities.

MYOTUBULE. An intermediate stage in muscle fiber development, where the fiber is tubular with a centrally placed nucleus, instead of a peripheral eccentric nucleus.

MYXEDEMA. Swelling of the face, hands, feet, and genitals due to hypothyroidism.

MYXOID. Resembling mucus.

N

N-ACETYLGLUCOSAMINE-1-PHOSPHOTRANSFERASE (GNPTA). Enzyme that attaches a signal to other enzymes and directs those enzymes to the lysosome; deficient in mucopolidoses II and III.

NANISM. Short stature.

NARCOTICS. Strong prescription medication that can be effective in treating pain, but have the potential to be habit-forming if their use is not supervised correctly.

NASOGASTRIC TUBE. A long flexible tube inserted through the nasal passageways, down the throat, and into the stomach. Used to drain the contents of the stomach.

NATURAL IMMUNITY. First line immune response that is non-specific. Includes action of phagocytes, natural killer cells, and complement cells.

NATURAL KILLER CELLS (NK CELLS). White blood cells that fight virally infected cells and tumor cells within the body.

NATURAL SELECTION. The evolutionary pressure that affects the survival and reproduction of individuals based on their differing phenotypes within a population.

NECROSIS. Death of a portion of tissue differentially affected by disease or injury.

NECROTIZING ENCEPHALOMYELOPATHY. A progressive degeneration of the brain and central nervous system. This condition is fatal in nearly all individuals affected with type A pyruvate carboxylase deficiency.

NECROTIZING PANNICULITIS. Raised bumps under the skin that develop into ulcers.

NEGATIVE SYMPTOMS. Symptoms of schizophrenia characterized by the absence or elimination of certain behaviors: affective flattening, poverty of speech, and loss of will or initiative.

NEONATAL. Neonatal refers to the first 28 days after birth.

NEONATE. A newborn infant up to six weeks of age.

NEONATOLOGIST. A physician (pediatrician) who has special training in the care of newborns (neonates).

NEOPLASIA. An abnormal proliferation of cells, which results in an abnormal mass of tissue known as a neoplasm.

NEOPLASM. An abnormal growth of tissue; for example, a tumor.

NEPHRECTOMY. Surgical removal of a kidney.

NEPHROCALCINOSIS. An abnormal increase in calcium levels in kidney tissue.

NEPHROLITHIASIS. The medical term for the process of kidney stone formation.

NEPHRON. Basic functional filtration unit of the kidney.

NEPHRONOPHTHISIS. An autosomal recessive genetic disorder of the kidneys that usually affects children.

NEPHROPATHY. Kidney disease.

NEPHROTIC SYNDROME. A kidney disorder characterized by high levels of protein in the urine, low levels of albumin in the blood, and edema (abnormal accumulation of fluid in the body). It may be caused by genetic mutations, infections, certain medications, or such other disorders as diabetes and cancer.

NERVE CONDUCTION TESTING. Procedure that measures the speed at which impulses move through the nerves.

NERVOUS SYSTEM. The complete network of nerves, sense organs, and brain in the body.

NEURAL. Pertaining to a nerve or the nervous system.

NEURAL CREST CELLS. A group of cells in the early embryo, located on either side of the area that will eventually develop into the spinal cord. The cells migrate (move) away from the area and give rise to various body structures, including melanocytes (pigment producing cells), certain structures of the face and head, and parts of the nervous system.

NEURAL FOLDS AND TUBE. Portions of the developing embryo from which the brain and spinal cord arise.

NEURAL TUBE DEFECTS (NTDS). A group of disorders in which an opening in the brain or spinal cord persists after the fourth week of fetal development.

NEUROCRISTOPATHY. A disorder that results from abnormal development and/or migration of the neural crest cells in the embryo.

NEUROFIBRILLARY TANGLES. Accumulations of twisted tau protein fragments inside nerve cells in the brain that are diagnostic of Alzheimer's disease.

NEUROFIBROMA. A soft tumor usually located on a nerve.

NEUROFIBROMATOSIS. A progressive genetic condition often including multiple café-au-lait spots, multiple raised nodules on the skin known as neurofibromas, developmental delays, slightly larger head sizes, and freckling of the armpits, groin area, and iris.

NEUROIMAGING. Imaging studies of the brain, such as x-ray, computed tomography (CT) scans, or magnetic resonance imaging (MRI) scans.

NEUROLEPTIC. Another name for the older type of antipsychotic medications given to schizophrenic patients.

NEUROLOGICAL. Relating to the brain and central nervous system.

NEUROLOGIST. A physician who specializes in disorders of the nervous system, including the brain, spine, and nerves.

NEUROMETABOLIC DISORDER. Any disorder or condition that affects both the CNS and the metabolism of the body.

NEUROMUSCULAR. Involving both the muscles and the nerves that control them.

NEUROMUSCULAR JUNCTION. The site at which nerve impulses are transmitted to muscles.

NEURON. The fundamental nerve cell that conducts impulses in the brain and nervous system.

NEURONAL CEROID LIPOFUSCINOSES. A family of eight genetically distinct progressive neurological disorders that are all a result of overaccumulation of lipopigments.

NEURONAL SPECTRINOPATHIES. Neurological disorders such as SPARCA1 and SCA5 that are caused by mutations in genes encoding brain spectrins.

NEUROPATHY. A general term for disorders of the nerves of the peripheral nervous system.

NEUROPROTECTIVE. Conveying some form of protection from injury to the nervous system.

NEUROTRANSMITTERS. Chemicals that carry nerve impulses from one nerve cell to another; Alzheimer's disease causes a drop in the production of several important neurotransmitters.

NEUTROPENIA. A condition in which the number of leukocytes (a type of white or colorless blood cell) is

abnormally low, mainly in neutrophils (a type of blood cell).

NEUTROPHIL. The primary type of white blood cell involved in inflammation. Neutrophils are a type of granulocyte, also known as a polymorphonuclear leukocyte.

NEVUS. The medical term for mole; it is derived from the Latin word for birthmark. (Plural: nevi.)

NEVUS FLAMMEUS. A flat blood vessel tumor present at birth, also known as a “port wine stain.”

NEWBORN SCREENING. The act of testing all infants for a specific disease shortly after birth for the purpose of preventing disease progression through prompt medical treatment.

NEXT-GENERATION SEQUENCING (NGS). A platform that allows for the simultaneous sequencing of a number of regions of interest in a patient’s DNA.

N-GLYCANASE 1. An enzyme encoded by the NGLY1 gene that removes (cleaves) sugars called glycans from misfolded proteins.

NITRATES/NITRITES. Chemical compounds found in certain foods and water that, when consumed, may increase the risk of gastric cancer.

NONDISJUNCTION. An error in chromosome separation that occurs during cell division resulting in a woman receiving an extra X chromosome, leading to triple X syndrome.

NONHOMOLOGOUS. Referring to chromosomes that are not members of the same pair.

NONINVASIVE PRENATAL TESTING (NIPT). A blood test administered to a pregnant woman to screen for an abnormal number of chromosomes (aneuploidy) in the developing fetus. It is also known as noninvasive prenatal screening or NIPS.

NONKETOTIC HYPERGLYCEINEMIA (NKH). Glycine encephalopathy.

NONRENAL HAMARTOMA. Benign (noncancerous) tumor-like growths not found in the kidneys that often disrupt the normal function of a particular organ system.

NONSPHEROCYTIC. Literally means not sphere-shaped. Refers to the shape of red blood cells in nonspherocytic hemolytic anemia.

NONSTEROIDAL ANTI-INFLAMMATORY DRUG (NSAID). A pain reliever, such as ibuprofen or naproxen.

NONSYNDROMIC HEARING LOSS (NSHL). Hereditary hearing loss that is not part of another underlying genetic disorder.

NONTRAUMATIC UNGUAL OR PERIUNGUAL FIBROMA. Fibrous growth that appears around the fingernails and/or toenails.

NOONAN SYNDROME. A genetic syndrome that possesses some characteristics similar to cardiofaciocutaneous syndromes. It is unclear whether the two syndromes are different or two manifestations of the same disorder.

NOSOLOGY. A branch of medicine that aims to classify diseases by means of disease etiology (cause), pathogenesis (mechanism), and/or symptoms.

NUCHAL. Referring to the nape of the neck.

NUCHAL TRANSLUCENCY. A pocket of fluid at the back of an embryo’s neck visible via ultrasound. When thickened, it may indicate that the infant will be born with a congenital heart defect.

NUCHAL TRANSLUCENCY ULTRASOUND. Specialized ultrasound imaging that looks for a larger-than-normal space and fluid at the back of the first-trimester fetal neck to screen for chromosomal abnormalities.

NUCLEAR DNA (DEOXYRIBONUCLEIC ACID). The genetic material that contains the instructions for creating proteins. The nuclear DNA is packaged into chromosomes and is found in the control center (nucleus) of the cell.

NUCLEAR GENOME. The complete set of nuclear DNA found in the nucleus of the cell.

NUCLEAR ISOLATE. An isolated preparation of the contents of the nucleus of a cell, which contains the DNA.

NUCLEASE. A type of enzyme responsible for breaking the chemical bonds between the subunits (nucleotides) that make up DNA and RNA. A specific nuclease called Cas9 is used in CRISPR genome editing technology.

NUCLEI. Plural for nucleus, a special part of the cell that is essential for cell function.

NUCLEIC ACIDS. Any of various acids (such as DNA or RNA) that are found in living cells.

NUCLEOSOME. A basic unit of DNA packaging consisting of a segment of DNA wrapped around eight histone proteins.

NUCLEOTIDE. A building block of a nucleic acid (DNA or RNA), consisting of a sugar molecule, a phosphate group, and one of the nitrogen-containing bases (adenine, cytosine, guanine, and thymine in DNA; adenine, cytosine, guanine, and uracil in RNA).

NUCLEUS. The central part of a cell that contains most of its genetic material, including chromosomes and DNA.

NYSTAGMUS. Involuntary rapid eye movements.

O

OBLIGATE CARRIER. An individual who, based on pedigree analysis, must carry a genetic mutation for a particular genetic disease. Parents of a child with an autosomal recessive disorder are obligate carriers.

OBSESSIVE-COMPULSIVE DISORDER (OCD). Disorder characterized by persistent, intrusive, and senseless thoughts (obsessions) or compulsions to perform repetitive behaviors that interfere with normal functioning.

OCCIPITAL LOBE. An anatomical subdivision, located at the back of the brain, that contains the visual cortex.

OCHRONOSIS. A condition marked by pigment deposits in cartilage, ligaments, and tendons.

OCULAR. A broad term that refers to structure and function of the eye.

OCULAR ALBINISM (OA). Forms of albinism that primarily affect the eyes.

OCULO. Related to the eye.

OCULO-DIGITAL REFLEX. A reflex causing an individual to press on his or her eyes with fingers or fists.

OCULOCUTANEOUS ALBINISM (OCA). Forms of albinism that can affect the hair, skin, and eyes; there are several inherited forms of OCA that are caused by defects in different genes.

OCULOMOTOR NERVE. Cranial nerve III; the nerve that extends from the midbrain to several of the muscles that control eye movement.

OFF-LABEL. The decision to prescribe a drug for purposes other than those specifically approved by the U.S. Food and Drug Administration.

OKIHIRO SYNDROME. An inherited disorder characterized by abnormalities of the hands and arms and hearing loss; may be associated with Duane retraction syndrome.

OLIGODACTYLY. The absence of one or more fingers on a hand or toes on a foot.

OLIGODENDROCYTE. A cell in the central nervous system that insulates the parts of nerve cells called axons.

OLIGODONTIA. The absence of one or more teeth.

OLIGOHYDRAMNIOS. A reduced amount of amniotic fluid. Causes include nonfunctioning kidneys and premature rupture of membranes. Without amniotic fluid to

breathe, a baby will have underdeveloped and immature lungs.

OLIGOSACCHARIDE. Several monosaccharide (sugar) groups joined by glycosidic bonds.

OLIGOSPERMIA. A low concentration of sperm in a semen sample, usually defined as fewer than 15 million sperm per milliliter.

OLLIER DISEASE. Also termed multiple enchondromatosis. Excessive cartilage growth within the bone extremities that results in benign cartilaginous tumors arising in the bone cavity.

OMPHALOCELE. A birth defect where the bowel and sometimes the liver protrudes through an opening in the baby's abdomen near the umbilical cord.

OMPHALOPAGUS. Conjoined twins who are attached at the abdomen.

ONCOGENE. A gene that allows the uncontrolled division and proliferation of cells that lead to tumor formation and often to cancer.

ONCOLOGY. The branch of medicine concerned with the study, diagnosis, treatment, and prevention of cancer.

ON-TARGET POINT MUTATION. The substitution of one DNA base for another or insertion or deletion of one base.

ONYCHOGRYPHOSIS. Overgrowth of the fingernails and toenails.

OOCYTE (PRONOUNCED OH-EH-SITE). A diploid cell in females from which an egg or ovum develops by meiosis.

OOGONIAL STEM CELLS. Cells that develop into mature eggs.

OPEN-ANGLE JUVENILE GLAUCOMA. Hereditary glaucoma that develops in childhood or early adulthood and can be caused by mutations in the *MYOC* or *CYP11* genes.

OPERON. A functional unit of genomic DNA containing several genes under the control of one promoter.

OPHTHALMOLOGIST. A physician specializing in the medical and surgical treatment of eye disorders.

OPHTHALMOLOGY. The medical specialty of vision and the eye.

OPHTHALMOSCOPE. An instrument with special lighting, designed to view structures in the back of the eye.

OPISTHOTONOS. An arched position of the body in which only the head and feet touch the floor or bed when the patient is lying on their back.

OPPORTUNISTIC INFECTIONS. Infections that would not usually cause illness in people with a healthy immune system.

OPTIC DISC. The circular area at the back of the eyeball where the optic nerve connects to the retina.

OPTIC NERVE. A bundle of nerve fibers that carries visual messages from the retina in the form of electrical signals to the brain.

OPTOMETRIST. A medical professional who examines and tests the eyes for disease and treats visual disorders by prescribing corrective lenses and/or vision therapy. In many states, optometrists are licensed to use diagnostic and therapeutic drugs to treat certain ocular diseases.

ORAL GLUCOSE TOLERANCE TEST (OGTT). A diabetes test that measures blood sugar at intervals after drinking a sugary solution.

ORAL LOADING TEST. A procedure in which cystine is administered orally to a patient and plasma levels of cystine are measured. Under normal circumstances, amino acids are absorbed by the intestine and result in an increase in plasma amino acid levels. However, in cystinuria, there is a problem in the absorption process and blood levels of amino acids do not rise or rise slowly after eating.

ORBITAL CYSTS. Small fluid-filled sacs that abnormally develop inside the bony cavity of the skull that holds the eyeball.

ORGAN. An organ is a group of cells that form a structure that has a specific function. For example, the heart, stomach, or brain.

ORGANELLE. A specialized structure found within a cell that performs a specific function or carries out a specific life process. Mitochondria are organelles.

ORGANIC ACIDURIA. The condition of having organic acid in the urine.

ORTHODONTIST. Dentist who specializes in the correction of misaligned teeth.

ORTHOKERATOLOGY. A method of reshaping the cornea using a contact lens. It is not considered a permanent method to reduce myopia.

ORTHOPEDIC. Pertaining to the field of orthopedics, the science of the bones and diseases of the bones.

ORTHOSTATIC. Posture that is maintained while standing.

ORTHOSTATIC HYPOTENSION. A sudden decrease in blood pressure upon sitting up or standing. It may be a side effect of several types of drugs.

ORTHOTICS. A field of science that deals with the use of external mechanical devices to support or assist weak or abnormal joints, limbs, or muscles.

OSMOLARITY. The concentration of an osmotic solution, especially when measured in osmoles or milliosmoles per liter of solution.

OSMOTICALLY. Referring to the movement of a solvent through a semipermeable membrane (as of a living cell) into a solution of higher solute concentration that tends to equalize the concentrations of solute on the two sides of the membrane.

OSSICLES. The three bones of the middle ear, including the malleus, incus, and stapes.

OSSIFICATION. The process of bone formation.

OSTEOARTHRITIS. A group of diseases and mechanical abnormalities involving degradation of joints.

OSTEOBLASTS. A bone cell that makes bone.

OSTEOCHONDROMATOSIS. Another name for hereditary multiple exostoses, meaning a growth of bone and cartilage.

OSTEOCLASTS. A bone cell that breaks down and reabsorbs bone.

OSTEODYSPLASIA. A general term for a disorder of bone development.

OSTEOGENIC SARCOMA. A form of cancer that originates in the bone.

OSTEOGENIC. Derived from or containing bone cells.

OSTEOMA. A bony tissue tumor, either benign or malignant.

OSTEOMALACIA. The medical term for bone softening in adults due to inadequate levels of dietary calcium or phosphate, or the resorption of calcium from the bones by excessive secretion of parathyroid hormone.

OSTEOPOROSIS. Loss of bone density that can increase the risk of fractures.

OTITIS MEDIA. Inflammation of the middle ear, often due to fluid accumulation secondary to an infection.

OTOLARYNGOLOGIST. A physician who specializes in the care of the ear, nose, and throat and their associated structures.

OTOSCLEROSIS. Growth of spongy bone in the inner ear that causes progressive hearing loss and deafness.

OVA. Another name for the egg cells that are located in the ovaries.

OVARIES. The female reproductive organs that produce the reproductive cells (ova) and female hormones.

OVULATION. The monthly process by which an ovarian follicle or cyst ruptures, releasing a mature egg cell.

OXALATE. A naturally occurring molecule in the human body and in nature, too much of which can cause kidney stones.

OXALOSIS. A metabolic process in the body that happens in patients with primary hyperoxaluria whose kidneys fail. When the body stops removing extra oxalate, it accumulates in the blood and organs and leads to serious complications.

OXYGENATED BLOOD. Blood carrying oxygen through the body.

OXYTOCIN. A hormone that stimulates uterine contractions during childbirth and the secretion of breast milk.

OZENA. Also called atrophic rhinitis, it is a condition in which the bony ridges and mucous membranes of the nose waste away (atrophy), resulting in a foul-smelling bacteria-infected discharge.

P

PACEMAKER. A medical device placed in the chest that helps regulate heart rate.

PACHYDERMA. An abnormal skin condition in which excess skin is produced that appears similar to that of an elephant (pachyderm).

PACHYGYRIA. The presence of a few broad gyri (folds) and shallow sulci (grooves) in the cerebral cortex.

PAGET'S DISEASE. A non-cancerous disease marked by excessive growth of abnormal bone material.

PALATE. The roof of the mouth.

PALLIATIVE. Treatment given for relief of symptoms rather than a cure.

PALMAR. Referring to the palms of the hand.

PALMOPLANTAR KERATODERMA. Group of mostly hereditary disorders characterized by thickening of the corneous layer of skin (hyperkeratosis) on the palms and

soles as a result of excessive keratin formation (protein in the skin, hair, and nails).

PALMOPLANTAR KERATOSIS. A raised thickening of the outer horny layer of the skin on the palms of the hands and the soles of the feet.

PALPEBRAL FISSURES. The opening between the upper and lower eyelids.

PALPITATIONS. Perceived rapid or abnormal heartbeats associated with awareness of the heart's contractions in the chest. Palpitations may be caused by anxiety, caffeine, some drugs of abuse, or certain prescription medications, as well as by structural abnormalities of the heart.

PALSY. Uncontrollable tremors.

PANCREAS. An organ located in the abdomen that secretes pancreatic juices for digestion and hormones for maintaining blood sugar levels.

PANCREATIC INSUFFICIENCY. Reduction or absence of pancreatic secretions into the digestive system due to scarring and blockage of the pancreatic duct.

PANCREATIC ISLET CELL. Cells located in the pancreas that serve to make certain types of hormones.

PANCREATITIS. Inflammation of the pancreas.

PANCYTOPENIA. An abnormal reduction in the number of erythrocytes (red blood cells), leukocytes (a type of white or colorless blood cell), and blood platelets (a type of cell that aids in blood clotting) in the blood.

PANHYPOPITUITARISM. Generalized deficiency of all of the anterior pituitary hormones.

PAPILLOMA. Any benign localized growth of the skin or the linings of the respiratory and digestive tracts. The most common papillomas are warts.

PAPILLOMATOUS PAPULES. Skin-colored, raised bumps (not warts) found on the skin; most of these growths are benign (noncancerous) and rarely become malignant (cancerous).

PAPULA. A small raised area of the skin that lacks visible fluid.

PARALYSIS. Complete loss of muscle function for one or more muscle groups, often with loss of feeling and mobility in the affected area.

PARAMUTATION. a heritable change in the expression of one allele that results from an interaction of this allele with another allele for the same trait. The paramutation affected allele can be passed to subsequent generations.

PARAPAGUS. Conjoined twins who are joined at the side of their lower bodies.

PARAPLEGIA. Impairment in the sensory or motor functions of the lower limbs.

PARASITIC TWINS. Twins who include a smaller, malformed twin who is dependent on the larger, stronger twin for survival.

PARASYMPATHETIC GANGLION CELL. Type of nerve cell normally found in the wall of the colon.

PARATHYROID GLANDS. A pair of glands adjacent to the thyroid gland that primarily regulate blood calcium levels.

PARENCHYMA. Functional (rather than structural) tissues of an organ.

PARESTHESIA. The sensation of prickling, burning, or “pins-and-needles” in the limbs.

PARKINSON'S DISEASE. A progressive disease occurring most often after the age of 50, associated with the destruction of brain cells that produce dopamine and characterized by tremor, slowing of movement, and gait difficulty.

PARKINSONISM. A set of symptoms originally associated with Parkinson disease that can occur as side effects of neuroleptic medications: trembling of the fingers or hands, a shuffling gait, and tight or rigid muscles.

PATAU SYNDROME. Trisomy 13; an extra chromosome 13.

PATELLA. The kneecap.

PATENT DUCTUS ARTERIOSUS (PDA). A congenital anomaly of the heart occurring when the ductus arteriosus (the temporary fetal blood vessel that connects the aorta and the pulmonary artery) does not close at birth.

PATERNAL. Relating to one's father.

PATHOGENESIS. The biological mechanism that leads to a disease or disorder, or the origin and development of the disease.

PATHOGENIC VARIANT. A mutation or variation in a gene that causes a genetic disorder.

PECTORALIS MUSCLES. Major muscles of the chest wall.

PECTUS CARINATUM. An abnormality of the chest in which the sternum (breastbone) is pushed outward. It is sometimes called “pigeon breast.”

PECTUS EXCAVATUM. An abnormality of the chest in which the sternum (breastbone) sinks inward; sometimes called “funnel chest.”

PEDIGREE. A genetic diagram of a family tree that shows the appearance of a trait or disorder across several generations.

PELVIC EXAMINATION. A physical examination performed by a physician, often associated with a Pap smear. The physician inserts his or her finger into a woman's vagina, attempting to feel the ovaries directly.

PENDRIN. A protein encoded by the *SLC26A4* gene located on chromosome 7q31. Pendrin protein is believed to transport iodide and chloride within the thyroid and the inner ear.

PENETRANCE. The proportion of individuals who actually exhibit a trait for which they have gene or gene variant.

PEPTIC ULCER. A wound in the bowel that can be caused by stomach acid or a bacterium called *Helicobacter pylori*.

PEPTIDASE. Any enzyme that breaks down proteins. The gene whose mutations cause CODAS syndrome codes for a peptidase enzyme. Peptidases are also called proteases.

PERCHLORATE DISCHARGE TEST. A test used to check for Pendred syndrome by measuring the amount of iodine stored inside the thyroid gland. Individuals with Pendred syndrome usually have more iodine stored than normal, and thus their thyroid will release a large amount of iodine into the bloodstream when they are exposed to a chemical called perchlorate.

PERCUSSION. A technique used in physical diagnosis in which the examiner taps on the surface of the body to determine the condition of the structure beneath the skin. Percussion is used when examining a patient for myotonia congenita to see whether the tapping will cause the muscle beneath the skin to contract.

PERICARDITIS. Inflammation of the pericardium, the membrane surrounding the heart.

PERINATOLOGIST. A physician (obstetrician) who has special training in managing difficult pregnancies. Some prenatal tests, such as chorionic villus sampling and level II ultrasound, are performed primarily by perinatologists.

PERIOD OF SUSCEPTIBILITY. The time when teratogens can cause harm to the developing fetus.

PERIODONTITIS. Inflammatory reaction of the tissues surrounding and supporting the teeth that can progress to bone destruction, abscess formation, and eventual tooth loss.

PERIORBITAL PURPURA. A purplish or brownish discoloration caused by bleeding from the fragile capillaries in the skin around the eyes.

PERIOSTEAL. Relating to the periosteum, which is the connective tissue that covers all human bones.

PERIPHERAL NERVES. Nerves throughout the body that communicate motor and sensory information to and from the spinal cord.

PERIPHERAL NEUROPATHY. Any disease of the nerves outside of the spinal cord, usually resulting in weakness and/or numbness.

PERIPHERAL VISION. The ability to see objects that are not located directly in front of the eye. Peripheral vision allows people to see objects located on the side or edge of their field of vision.

PERITONEAL DIALYSIS. A form of therapy for kidney disorders that involves using the patient's abdomen (peritoneal cavity) as the site of treatment. Fluid is infused into the abdomen through a catheter and remains in the abdomen for several hours while waste products diffuse into the fluid from the abdominal blood vessels. The fluid is then removed and replaced with fresh fluid four to six times per day.

PERITONITIS. Inflammation of the peritoneum, the membrane surrounding the abdominal contents.

PERNICIOUS ANEMIA. A blood condition with decreased numbers of red blood cells related to poor vitamin B12 absorption.

PERONEAL. The outer part of the leg.

PEROXISOME. A cellular organelle containing different enzymes responsible for the breakdown of waste or other products.

PERSONALIZED MEDICINE. The tailoring of medical treatment to the individual patient based on his or her genetic profile. It is also called precision medicine.

PERVASIVE DEVELOPMENTAL DISORDER NOT OTHERWISE SPECIFIED (PDD-NOS). A term previously used to describe individuals who met some but not all of the criteria for classic autism or Asperger syndrome; now classified as an ASD.

PES PLANUS. Flat feet.

PEUTZ-JEGHERS SYNDROME (PJS). An inherited syndrome causing polyps in the digestive tract and spots on the mouth as well as increased risk of cancer.

PHAGOCYTE. White blood cells capable of engulfing and destroying foreign antigen or organisms in the fluids of the body.

PHALANGES. Long bones of the fingers and toes, divided by cartilage around the knuckles.

PHALILALIA. Involuntary echoing of the last word, phrase, sentence, or sound vocalized by oneself.

PHARMACODYNAMICS. Study of how a drug affects the body.

PHARMACOGENETICS. The study of how medication metabolism is affected by genetic inheritance.

PHARMACOGENOMICS. The branch of medicine that studies the role of the human genome in response to medications.

PHARMACOKINETICS. Study of how the body breaks down and uses a drug.

PHENOTYPE. The physical expression of an individual's genes.

PHENYLALANINE (PHE). An essential amino acid that must be obtained from food since the human body cannot manufacture it.

PHENYLALANINE HYDROXYLASE. The enzyme responsible for converting dietary phenylalanine to tyrosine. If phenylalanine hydroxylase is not working efficiently, phenylalanine levels in the blood increase.

PHENYLKETONURIA (PKU). An inherited inability to metabolize dietary phenylalanine, resulting in blood phenylalanine levels above 20 mg/dL. If left untreated, elevated blood phenylalanine levels can result in damage to the nervous system, including severe cognitive impairment, often referred to as intellectual disability.

PHEOCHROMOCYTOMA. A small vascular tumor of the inner region of the adrenal gland. The tumor causes uncontrolled and irregular secretion of certain hormones.

PHILTRUM. The grooved space between the nose and the upper lip.

PHLEBOTOMIST. A nurse or other health-care worker with special training in drawing venous blood for testing or analysis.

PHLEBOTOMY. The taking of blood from the body through an incision in the vein, usually in the treatment of disease.

PHOBIA. An exaggerated fear.

PHOSPHORIBOSYLPYROPHOSPHATE (PRPP). A molecule that is required for making new purine and pyrimidine nucleotides and for salvaging and recycling purines; PRPP synthesis requires phosphoribosylpyrophosphate synthetase 1 (PRPP synthetase 1), which is encoded by the *PRPS1* gene.

PHOSPHORYLATION. The addition of a phosphate group to a protein molecule. Protein phosphorylation plays an important role in many biological processes, including the activation of growth factor receptors.

PHOTOPHOBIA. Extreme sensitivity to light.

PHOTOPIGMENT. Pigment that is most sensitive to a particular wavelength of light.

PHOTORECEPTOR. Cells at the back of the eye that process the light that hits them; examples are cone and rod cells.

PHOTORECEPTOR CELLS. Specialized cells that convert light into nerve signals that ultimately get transmitted to the brain through the optic nerve.

PHOTOREFRACTIVE KERATECTOMY (PRK). A procedure that uses an excimer laser to make modifications to the cornea and permanently correct myopia.

PHOTOSENSITIVITY. Sensitivity to light.

PHYTANIC ACID. A substance found in various foods that, if allowed to accumulate, is toxic to various tissues. It is metabolized in the peroxisome by phytanic acid hydroxylase.

PHYTANIC ACID HYDROXYLASE. A peroxisomal enzyme responsible for processing phytanic acid. It is defective in Refsum disease.

PIERRE ROBIN SEQUENCE. A malformation of the jaw, mouth, and tongue that includes a cleft palate, a small lower jaw (micrognathia), and a tongue set too far back in the mouth. It is named for Pierre Robin, the French physician who first described the sequence in 1923.

PIERSON SYNDROME. A rare genetic disorder characterized by congenital nephrotic syndrome as well as congenital microcoria. It is named for Michel Pierson, the French physician who first described it in 1963.

PITUITARY GLAND. A small gland at the base of the brain that is responsible for releasing many hormones, including luteinizing hormone (LH) and follicle-stimulating hormone (FSH).

PLACENTA. The organ responsible for oxygen and nutrition exchange between a pregnant mother and her developing baby.

PLANTAR. Referring to the sole of the foot.

PLASMA. The liquid part of the blood and lymphatic fluid that contains antibodies and other proteins.

PLASMA CELLS. White blood cells that originate in the bone marrow and secrete large quantities of antibodies.

PLASMALOGENS. The fat molecules that are important components of cells and of the myelin sheath that protects nerve cells.

PLASMAPHERESIS. A procedure in which the fluid component of blood is removed from the bloodstream and sometimes replaced with other fluids or plasma.

PLASMIN. The blood protein that is responsible for dissolving blood clots.

PLATELETS. Small disc-shaped structures that circulate in the blood stream and participate in blood clotting.

PLEURITIS. Inflammation of the pleura, the membrane surrounding the lungs.

PLOIDY. The number of sets of chromosomes in the nucleus of a cell.

PLURIPOTENT STEM CELLS. Can develop into any type of cell in the body and have the ability to replicate themselves.

PNEUMONIA. An infection of the lungs.

PNEUMOTHORAX. Abnormal accumulation of air in the chest cavity, outside the lung, often responsible for a collapsed lung.

PODOCYTES. Specialized cells in the Bowman's capsule of the kidney that wrap around the capillaries in the glomerulus and serve to prevent large protein molecules from passing into the urine while allowing water and small molecules like salt to pass through.

POIKILODERMA. A condition characterized by skin atrophy, widening of the small blood vessels (telangiectasia), and pigment changes giving a mottled appearance.

POIKILOTHERM. A term applied to any animal that cannot regulate its core body temperature and has a body temperature that varies with its surroundings. The opposite is a homeotherm, which refers to an organism (including humans) that can maintain a warm and fairly constant body temperature independent of the surrounding temperature.

POINT MUTATION (DNA). An error in the DNA sequence where one DNA base is substituted for another or inserted or deleted. This can sometimes cause the production of an abnormal protein or absence of a protein.

POLAR BODY. Either of two small cells produced during the two meiotic divisions in the production of an oocyte. Polar bodies contain only small amounts of cytoplasm and eventually disintegrate.

POLYARTERITIS NODOSA (PAN). An inflammatory disease that affects all layers of blood vessel walls and may be caused by *CECR1* gene mutations.

POLYCYSTIC OVARY SYNDROME (PCOS). A multifactorial disorder in women characterized by absent or infrequent ovulation, hirsutism (excessive body hair), infertility, acne, and increased susceptibility to obesity and type 2 diabetes.

POLYDACTYLY. The presence of extra fingers or toes.

POLYGENIC. Referring to an inherited disorder or trait whose phenotype is influenced by more than one gene.

POLYHYDRAMNIOS. A condition in which there is too much fluid around the fetus in the amniotic sac, seen in about 1% of pregnancies.

POLYMER. A very large molecule, formed from many smaller, identical molecules.

POLYMERASE CHAIN REACTION (PCR). A laboratory process used to make a large number of copies of specific genetic information from small amounts of DNA.

POLYMORPHIC. Describes a gene for which there exist multiple forms, or alleles.

POLYMORPHISM. A variation in a gene or chromosome that occurs with fairly high frequency in the general population.

POLYMYOSITIS. An inflammation of many muscles.

POLYNEUROPATHY. A disorder in which a number of nerves in the peripheral nervous system malfunction simultaneously.

POLYP. An abnormal tissue growth arising from a mucous membrane. The formation of an unusually large number of polyps is called polyposis.

POLYPECTOMY. Surgical removal of polyps.

POLYPLOIDY. A condition in which the nucleus of a cell contains more than two paired sets of chromosomes.

POLYPOSIS. The formation of numerous polyps in a body structure, most often the digestive tract or the nasal passages.

POLYSACCHARIDE. A linear or branched macromolecule composed of numerous monosaccharide (sugar) units linked by glycosidic bonds.

POLYSYNAPTIC CORTICAL PATHWAYS. The pathway by which stimuli enter the brain.

POLYSYNDACTYLY. Having both extra digits (toes, fingers) as well as webbing (syndactyly) between the digits.

PONS. A mass of nerve fibers in the brain stem that relay nerve impulses between the cerebellum and the rest of the brain.

PONTOCEREBELLAR HYPOPLASIA (PCH). Underdevelopment of the pons and cerebellum of the brain; PCH10 is caused by a mutation in the *CLP1* gene.

POOR MUSCLE TONE. The condition of muscles that are weak and floppy.

PORENCEPHALY. A congenital anomaly of the brain in which there are abnormal holes or cavities in the brain.

PORPHYRIA. Any one of a number of diseases, usually genetic in character, in which the conversion of porphyrins to heme is disrupted; usually associated with neurological problems.

PORPHYRIN. A large cyclic molecule shaped like a four-leaf clover. Combined with an iron atom, it forms a heme molecule.

PORT-WINE STAIN. Dark-red birthmarks seen on the skin, named after the color of the dessert wine.

POSER CRITERIA. Criteria proposed in 1983 as an update to the Schumacher criteria for diagnosing MS; developed to aid neurologists in determining the existence of lesions and other para-clinical evidence of MS.

POSITIONAL CLONING. Cloning a gene simply on the basis of its position in the genome, without having any idea of the function of the gene.

POSITIVE SYMPTOMS. Symptoms of schizophrenia that are characterized by the production or presence of behaviors that are grossly abnormal or excessive, including hallucinations and thought-process disorder.

POSITRON EMISSION TOMOGRAPHY (PET). A form of nuclear medicine scanning that measures brain activity using low doses of a radioactive substance.

POST-AXIAL POLYDACTYLY. An extra finger or toe on the outside of the hand or foot.

POSTERIOR FOSSA. The area at the base of the skull attached to the spinal cord.

POST-ICTAL STATE. A period of lethargy, confusion, and deep breathing following a grand mal seizure that may last from a few minutes to several hours.

POVERTY OF SPEECH. A negative symptom of schizophrenia, characterized by brief and empty replies to questions.

PRADER-WILLI SYNDROME (PWS). A disorder caused by the deletion or absence of active imprinted genes.

PREAURICULAR PITS. Small pits in the skin on the outside of the ear.

PRE-AXIAL POLYDACTYLY. An extra finger or toe on the inside of the hand or foot.

PREBIOTIC. Chemicals or compounds that induce growth in micro-organisms.

PRECISION MEDICINE. An approach to health care that bases the prevention and treatment of disease on each individual's unique genetic makeup and lifestyle habits. It is sometimes called personalized medicine.

PRECOCIOUS PUBERTY. An abnormal condition in which a person undergoes puberty at a very young age. This condition causes the growth spurt associated with puberty to occur before the systems of the body are ready, which causes these individuals to not attain normal adult heights.

PRECURSOR COMPONENTS. Components in an enzymatic pathway that are formed by previous cellular events.

PREFRONTAL CORTEX (PFC). The anterior gray matter of the frontal lobe of the brain that regulates complex cognition, emotions, and behaviors.

PREGNANCY-ASSOCIATED PLASMA PROTEIN A (PAPP-A). An early pregnancy protein in maternal blood and urine; fetal chromosomal abnormalities can cause decreased PAPP-A levels.

PREIMPLANTATION GENETIC TESTING (PGT). A screening test performed on embryos created by IVF to analyze the genetics of each embryo prior to transfer into the intended mother's uterus. Also called preimplantation genetic diagnosis (PGD).

PREMATURE OVARIAN INSUFFICIENCY (POI). Premature ovarian failure; the cessation of ovarian function before age 40.

PREMUTATION. A change in a gene that precedes a mutation; this change does not alter the function of the gene.

PRENATAL DIAGNOSIS. The determination of whether a fetus possesses a disease or disorder while it is still in the womb.

PRENATAL TESTING. Testing for a disease such as a genetic condition in an unborn baby.

PRENATAL ULTRASOUND. An imaging test using high-frequency sound waves to create images of internal organs. "Prenatal" indicates the test is performed on a fetus while still in the womb.

PRESENILIN (PS-1 OR PS-2). Proteins involved in processing amyloid precursor protein; mutations in the genes encoding these proteins can cause early-onset familial Alzheimer's disease.

PREVALENCE. The number of individuals living with a particular illness within a particular population at any

given time. Prevalence is often expressed in terms of number of individuals per 100 or per 1,000 members of the population.

PRIMARY ATRIAL SEPTATION. An improper division of the atria of the heart, or a "hole in the heart," which results in the formation of a common atrium rather than the normal two-chambered atrium.

PRIMARY CANCER. The first or original cancer site before any metastasis.

PRIMARY CONGENITAL GLAUCOMA (PCG). Glaucoma that is present at birth or develops during the first year of life and can be caused by mutations in the *CYPB1* or *LTBP2* genes.

PRIMARY CRANIOSYNOSTOSIS. Abnormal closure of the cranial sutures caused by an abnormality in the sutures themselves.

PRIMARY IMMUNE DEFICIENCY DISEASES (PIDDs). A group of rare genetic disorders caused by inherited defects in specific cells of the immune system. XMEN is one of about 200 known PIDDs. Also referred to as primary immunodeficiency diseases (PIDs).

PRIMARY POSITION, PRIMARY GAZE. When both eyes are looking straight ahead.

PRIMARY TUMOR. The organ or tissue where a tumor began.

PRIMORDIAL. Referring to conditions that begin before birth or are characteristic of the embryo's earliest stages of development.

PRION. A protein that can fold in several different and distinctive ways, one of which can be transmitted to other proteins.

PROBAND. In genetics, a particular subject (person or animal) being reported on or studied. In most cases, the proband is the first affected member of a family with a genetic disorder who brings the condition to the attention of doctors and researchers.

PROBIOTIC. Micro-organisms believed to provide health benefits to humans.

PROCOLLAGEN. A collagen precursor formed by the twisting together of three pro-alpha1(II) chains.

PROGERIA. Genetic abnormality that presents initially as premature aging and failure to thrive in children.

PROGNATHISM. A protruding lower jaw.

PROGRAMMABLE NUCLEASES. DNA or RNA cutting enzymes from bacteria that can be programmed for

genome editing to cut at a specific location and stimulate changes in the sequence.

PROHORMONE. A precursor of a more active hormone. Thyroxine is the prohormone of triiodothyronine.

PROLACTIN. A hormone that helps the breast prepare for milk production during pregnancy.

PROLIFERATION. The growth or production of cells.

PROMOTER. The region of a gene that initiates transcription of the genetic information.

PRONUCLEAR TRANSFER. A mitochondrial replacement technique in which the mother's egg is first fertilized by the father's sperm; then the two pronuclei are inserted into a donor egg that has been fertilized and has had its own nucleus removed.

PRONUCLEUS. The nucleus of a sperm or egg cell during the process of fertilization.

PROPHYLACTIC. Referring to a medical or surgical intervention intended to prevent rather than treat disease.

PROPIONIC ACID. An organic compound that builds up in the body if the proper enzymes are not present.

PROPIONYL COA CARBOXYLASE. An enzyme that breaks down the amino acids isoleucine, valine, threonine, and methionine.

PROPORTIONATE DWARFISM. Dwarfism in which the person's body parts are all smaller or shorter than normal but remain in proportion to one another.

PROPTOSIS. Bulging of the eye outward from the orbit of the eye. It is also known as exophthalmos.

PROSTATECTOMY. The surgical removal of the prostate gland.

PROTEIN. Important building blocks of the body composed of amino acids, involved in the formation of body structures and controlling the basic functions of the human body.

PROTEIN TYROSINE PHOSPHATASE (PTP). A member of a protein family, including the PTEN protein, that modifies other proteins by removing a phosphate group.

PROTEINURIA. An abnormally high level of protein in the urine, defined as higher than 3.5 grams per day in adults or higher than 40 mg/m² per hour in children.

PROTEOLIPID PROTEIN GENE (PLP). A gene that makes a protein that is part of the myelin in the central nervous system. variants in this gene cause PMD.

PROTEOLYSIS. The breakdown of proteins into smaller units, usually polypeptides or amino acids.

PROTOCOL. A set of guidelines for medical tests or treatments.

PROTO-ONCOGENE. A gene involved in stimulating the normal growth and division of cells in a controlled manner.

PROTOPORPHYRIN. A precursor molecule to the porphyrin molecule.

PROTOSPACER. A regularly sized piece of phage DNA that has been excised and incorporated into the CRISPR array.

PROTOSPACER-ADJACENT MOTIFS (PAMS). Highly conserved short DNA sequences (2bp–5bp) that are necessary for the excision of adjacent protospacers.

PROTOZOA. One type of a class of single-celled organism.

PROXIMAL. Near the point of origin.

PROXIMAL 18Q. A deletion within the long arm of chromosome 18, near the centromere.

PROXIMAL MUSCLES. The muscles closest to the center of the body.

PSEUDOAUTOSOMAL DOMINANT INHERITANCE. The pattern of inheritance for a disorder caused by genes in the pseudoautosomal regions of the sex chromosomes. Individuals only require one mutated or nonworking copy of a gene to have signs and symptoms of the disorder. Affected individuals have a 50% chance to have an affected child with each pregnancy.

PSEUDOAUTOSOMAL REGION. Genes found on the sex chromosomes that contain the same genetic information whether they are on the X or Y chromosome.

PSEUDOCAMPTODACTYLY. A condition in which the fingers curve or bend when the hand is bent back at the wrist.

PSEUDOCYST. A fluid-filled space that may arise in the setting of pancreatitis.

PSEUDOSYNDACTYLY. A joining together of the fingers or toes from scarring that can occur with severe forms of epidermolysis bullosa.

PSORIASIS. A common, chronic, scaly skin disease.

PSYCHODYNAMIC THERAPIES. A form of psychological counseling that seeks to determine and resolve the internal conflicts that may be causing an individual to be suffering from symptoms of depression.

PSYCHOGENIC NON-EPILEPTIC SEIZURE (PNES). An event that resembles an epileptic seizure but lacks the electrical discharge associated with epilepsy. PNES is

associated with psychiatric disorders, most often conversion disorder, and is often triggered by a psychological trauma of some kind.

PSYCHOLOGIST. An individual who specializes in the science of the mind.

PSYCHOMOTOR. Movement produced by action of the mind or will.

PSYCHOSIS. A severe mental disorder characterized by loss of contact with reality, causing deterioration of normal social functioning.

PSYCHOTHERAPY. Psychological counseling that seeks to determine the underlying causes of a patient's depression. The form of this counseling may be cognitive/behavioral, interpersonal, or psychodynamic.

PSYCHOTIC DISORDER. A mental disorder characterized by delusions, hallucinations, or other symptoms of lack of contact with reality.

PTERYGIUM COLLI. Webbing or broadening of the neck, usually found at birth and usually on both sides of the neck.

PTOSIS. Drooping of the upper or lower eyelid.

PUBERTY. The stage of development when the gonads begin to function and secondary sexual characteristics begin to appear.

PULMONARY. Relating to the lungs; the pulmonary artery carries blood from the heart to the lungs.

PULMONARY ARTERY. An artery that carries blood from the heart to the lungs.

PULMONARY ATRESIA. A congenital malformation of the pulmonary valve in which the opening of the valve fails to develop. As a result, blood cannot flow out of the heart through the pulmonary artery to the lungs to be oxygenated.

PULMONARY EDEMA. A problem caused when fluid backs up into the veins of the lungs. Increased pressure in these veins forces fluid out of the vein and into the air spaces (alveoli). This interferes with the exchange of oxygen and carbon dioxide in the alveoli.

PULMONARY EMBOLISM. A blood clot in the lungs.

PULMONARY HYPERTENSION. A severe form of high blood pressure caused by diseased arteries in the lung.

PULMONARY HYPOPLASIA. Underdevelopment of the lungs.

PULMONARY STENOSIS. Narrowing of the pulmonary valve of the heart, between the right ventricle and the

pulmonary artery, limiting the amount of blood going to the lungs.

PULMONOLOGIST. A physician who specializes in lung diseases.

PULSENET. A network of laboratories across the United States, overseen by the Centers for Disease Control and Prevention (CDC) to identify bacteria responsible for foodborne outbreaks by using whole-genome sequencing.

PUNCTATED. Having a dotted pattern.

PUNNETT SQUARE. A grid used to determine the probability that the offspring of two parents with a single-gene trait being crossed will have a particular genotype. The square is named for Reginald Punnett, a British geneticist who first devised it in 1905.

PUPIL. The opening in the iris through which light enters the eye.

PURINES. A group of organic compounds that are important building blocks of RNA and DNA. Two of the four nucleobases found in DNA (adenine and guanine) are purines.

PURPURA FULMINANS. Dark, reddish-purple patches of dying tissue that result from clots in small blood vessels that would otherwise feed that tissue.

PUSTULE. A pus-filled lesion of the skin that resembles the "pimples" of adolescent acne.

PYELONEPHRITIS. Inflammation of the kidney commonly caused by bacterial infections.

PYGOPAGUS. Conjoined twins who are joined back-to-back with fused buttocks.

PYLORIC SPHINCTER. Circular smooth muscle found at the outlet of the stomach.

PYLORIC STENOSIS. Narrowing of the stomach due to thickening of the pyloric muscle at the end of the stomach.

PYOGENIC. Pus-forming.

PYREXIA. A medical term denoting fevers.

PYRIDOSTIGMINE BROMIDE (MESTINON). An anticholinesterase drug used in treating myasthenia gravis.

PYRUVATE CARBOXYLASE. The enzyme that is responsible for the first step in the conversion of pyruvate molecules into glucose molecules. Individuals with Type A PCD produce an highly inefficient form of pyruvate carboxylase. Individuals with Type B PCD either completely lack the ability to produce this enzyme,

or they cannot produce it in sufficient quantities to sustain life.

PYRUVATE DEHYDROGENASE COMPLEX. A series of enzymes and co-factors that allow pyruvate to be converted into a chemical that can enter the TCA cycle.

Q

QT INTERVAL. The section on an electrocardiogram between the start of the QRS complex and the end of the T wave, representing the firing or depolarization of the ventricles and the period of recovery prior to repolarization or recharging for the next contraction.

QUADRIPLÉGIA. Paralysis of all four limbs.

R

R117. A minor mutation in the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene that can cause absence of vas deferens without causing cystic fibrosis.

RACHITIC. Pertaining to, or affected by, rickets. Examples of rachitic deformities include curved long bones with prominent ends, a prominent middle chest wall, or bony nodules at the inner ends of the ribs.

RACIAL DISPARITIES. Inequities and inconsistencies in the way people are treated based on the color of their skin, in terms of socioeconomic status, education, access to health care, housing, and other aspects of life.

RADIAL KERATOTOMY (RK). A surgical procedure involving the use of a diamond-tipped blade to make several spoke-like slits in the peripheral (non-viewing) portion of the cornea to improve the focus of the eye and correct myopia by flattening the cornea.

RADIATION THERAPY. Treatment using high-energy radiation from x-ray machines, cobalt, radium, or other sources.

RADICULOPATHY. A bulging of disc material often irritating nearby nerve structures resulting in pain and neurologic symptoms. A clinical situation in which the radicular nerves (nerve roots) are inflamed or compressed. This compression by the bulging disc is referred to as a radiculopathy. This problem tends to occur most commonly in the neck (cervical spine) and low back (lumbar spine).

RADIOGRAPHIC. Involving an x-ray.

RADIOLUCENT. Transparent to x-ray or radiation. The black area on x-ray film.

RADIUS. One of the two bones of the forearm, the one adjacent to the base of the thumb.

RANSON CRITERIA. A system of measurements, including age and blood testing, that can be used to predict the outcome of a person who has been hospitalized for an episode of pancreatitis.

RAYNAUD'S PHENOMENON/RAYNAUD'S DISEASE. A condition in which blood flow to tissues is reduced by a malfunction of the nerves that regulate the constriction of blood vessels. When attacks of Raynaud's occur in the absence of other medical conditions, it is called Raynaud's disease. When attacks occur as part of a disease, as in scleroderma, it is called Raynaud's phenomenon.

RB1. A cell-cycle control and tumor-suppressor gene; deletion or mutation of RB1 can lead to retinoblastoma.

RECEPTOR. A molecule in or on the surface of a cell that recognizes and binds with specific molecules, such as hormones, neurotransmitters, or drugs.

RECESSIVE. Refers to a genetic trait that is expressed only when present on both members of a pair of genes, one inherited from each parent.

RECESSIVE DISEASE. Condition caused by a pathogenic variant (mutation) in both copies of a particular gene. Two carriers of an autosomal recessive condition have a one-in-four (25%) chance of passing it on to their children.

RECESSIVE GENE. A type of gene that is not expressed as a trait unless inherited by both parents.

RECESSIVE TRAIT. An inherited trait or characteristic that is outwardly obvious only when two copies of the gene for that trait are present.

RECOMBINATION. The production of genetic combinations in offspring that are different from those of the parents. This process occurs during meiosis.

RECTAL SUCTION BIOPSY. The removal and examination of a sample of rectum tissue for diagnostic purposes.

RECTUM. The end portion of the intestine that leads to the anus.

RECURRENCE RISK. The possibility that the same event will occur again.

RECURRENT. Tending to repeat.

RED BLOOD CELL (RBC). Hemoglobin-containing blood cells that transport oxygen from the lungs to tissues. In the tissues, the red blood cells exchange their oxygen for carbon dioxide that is then brought back to the lungs.

RED NUCLEUS. A small structure present in the brain stem that is involved in the control of movement.

REFRACTION. The bending of light rays as they pass from one medium through another. Used to describe the action of the cornea and lens on light rays as they enter the eye. Also used to describe the determination and measurement of the eye's focusing system by an optometrist or ophthalmologist.

REFRACTIVE EYE SURGERY. A general term for surgical procedures that can improve or correct refractive errors by permanently changing the shape of the cornea.

REMISSION. The time during which symptoms of a disease or condition are reduced or not present.

RENAL. Pertaining to the kidneys.

RENAL AGENESIS. Absence or failure of one or both kidneys to develop normally.

RENAL ANGIOMYOLIPOMA. Benign (noncancerous) tumors in the kidney that are made up of vascular tissue (angio), smooth muscle (myo), and fat (lipoma).

RENAL CALCULUS (PLURAL, CALCULI). The medical term for a kidney stone. Kidney stones are formed from minerals dissolved in the urine.

RENAL CELL CARCINOMA. A cancerous tumor made from kidney cells.

RENAL COLIC. A spasmodic pain, moderate to severe in degree, located in the back, side, and/or groin area.

RENAL CYSTS. Fluid or air-filled spaces within the kidneys.

RENAL DYSPLASIA. A developmental anomaly of the kidney.

RENAL HYPOPLASIA. Abnormally small kidneys.

RENAL SYSTEM. The organs involved with the production and output of urine.

RENAL TUBULAR DISORDER. Various defects in the renal tubular transport processes and their regulation.

RENIN. An enzyme produced by the kidneys.

RENPENNING SYNDROME. X-linked intellectual disability with short stature and microcephaly not associated with the fragile X chromosome and occurring more

frequently in males, although some females may also be affected.

REPLICATION. The process by which a virus makes copies of itself.

REPOLARIZATION. Period when the heart cells are at rest, preparing for the next wave of electrical current (depolarization).

REPRODUCIBILITY. A major principle of the scientific method, used to confirm the validity of a new discovery by repeating the research that produced it.

REPRODUCTIVE ENDOCRINOLOGIST. A doctor (usually a gynecologist) with subspecialty training in hormonal functioning as it pertains to infertility.

RESECTION. The act of removing an organ or tissue surgically.

RESIDUAL RISK. The chance that an individual may still be a carrier for a certain condition even though the person screened negative.

RESPIRATORY. Having to do with breathing.

RETICULOCYTE. Immature red blood cells.

RETINA. The light-sensitive layer of tissue in the back of the eye that receives and transmits visual signals to the brain through the optic nerve.

RETINAL ACHROMIC PATCH. Defect in the coloration of the retina.

RETINAL DYSPLASIA. Improper development of the retina that can lead to detachment of the retina.

RETINAL DYSTROPHY. Degeneration of the retina, causing a decline in visual clarity.

RETINAL HAMARTOMAS. Benign (noncancerous) tumor found on the retina.

RETINAL LACUNAE. Small abnormal cavities or holes in the retina.

RETINAL PIGMENT EPITHELIUM (RPE). The pigmented cell layer that nourishes the retinal cells; located just outside the retina and attached to the choroid.

RETINITIS PIGMENTOSA. Progressive deterioration of the retina, often leading to vision loss and blindness.

RETINOBLASTOMA. A cancerous tumor of the eye.

RETINOID. A derivative of synthetic vitamin A.

RETINOPATHY. Any disorder of the retina.

RETT SYNDROME. An inherited progressive neurodevelopmental disorder that affects females, usually

beginning in infancy, and characterized by slow brain growth, cognitive and motor deterioration, and possibly ASD.

REVERSE TRANSCRIPTASE. An enzyme that makes DNA from an RNA template.

RH FACTOR. Rhesus factor, a protein on the surfaces of red blood cells of many people; if the fetus is Rh-positive but the mother is Rh-negative, the mother must be treated with immune globulin to prevent the production of antibodies that will cross the placenta and attack the fetal blood cells.

RHABDOMYOLYSIS. Breakdown or disintegration of muscle tissue.

RHABDOMYOSARCOMA. A malignant tumor of the skeletal muscle.

RHEUMATOID ARTHRITIS (RA). A chronic autoimmune disease marked by inflammation of the membranes surrounding joints.

RHEUMATOID FACTOR. Antibodies present in the majority of individuals with rheumatoid arthritis. A diagnostic marker for rheumatoid arthritis that is absent from ankylosing spondylitis and other seronegative spondyloarthropathies.

RHIZOMELIC. Term meaning “root limb,” which refers to the disproportionate shortening of the upper part of a limb compared to the lower part.

RHO/RAC GUANINE EXCHANGE FACTOR. Member of a class of proteins that appear to convey signals important in the structure and biochemical activity of cells.

RHOGAM. The trade name of a medication given by intramuscular injection to a pregnant woman to prevent Rh disease in the newborn. Its generic name is Rho (D) immune globulin.

RIBONUCLEIC ACID (RNA). The genetic material that is involved in creating proteins. During the creation of proteins, one of the strands of the double stranded DNA sequence is transcribed into single-stranded RNA, which is involved in creating proteins. In the RNA sequence, a base called uracil (U) replaces thymine (T) when it is found in the DNA sequence.

RIBOSOME. A complex molecule made of RNA and proteins that acts like a protein synthesis factory.

RICKETS. A childhood disease caused by vitamin D deficiency, resulting in soft and malformed bones.

RING. A structural chromosomal abnormality in which a portion of a chromosome breaks off and its

ends join to form a circle or ring. There may or may not be loss of genetic material in a ring chromosome.

RING CHROMOSOME. An abnormal chromosome in which the terminal ends of the short (p) and long (q) arms have been lost and the remaining p and q arms subsequently join to form a ring.

RING SIDEROBLAST. A sideroblast that contains five or more iron granules in its mitochondria, enough to form a ring surrounding a third or more of the cell nucleus. It is also called a ringed sideroblast.

ROBERTSONIAN TRANSLOCATION. A chromosomal abnormality in which the long (q) arms of two acrocentric chromosomes (chromosomes in which the p arm is much shorter than the q arm; in humans, these are chromosomes 13, 14, 15, 21, and 22, and the Y chromosome) fuse together. The anomaly is named for William R.B. Robertson (1881–1941), who first identified it in grasshoppers in 1916.

ROD. A photoreceptor that is highly sensitive to low levels of light and transmits images in shades of gray.

ROLLER-TUBE TECHNIQUE. A technique used in tissue culture in which test tubes containing tissue or cell samples are held in a wheel-shaped instrument at a 15° angle from the horizontal, and the wheel is rotated vertically every 2 minutes. George Gey developed this technique in 1933.

ROSENTHAL FIBERS. Abnormal and irregularly shaped structures that form in astrocytes.

RUSSELL SYNDROME. An alternative term for Russell-Silver syndrome. Many doctors use this term to mean a Russell-Silver syndrome affected individual who does not have body asymmetry.

S

SACROILIAC JOINT. The joint between the triangular bone below the spine (sacrum) and the hip bone (ilium).

SACROILIITIS. Inflammation of the sacroiliac joint.

SACRUM. Triangular bone at the base of the spinal column.

SADDLE NOSE. A sunken nasal bridge.

SANGER SEQUENCING. The earliest method for sequencing DNA, devised by Frederick Sanger in the United Kingdom in 1977 and used as the primary method of sequencing until 2002. It is still used to validate the results of so-called next-generation sequencing. The Sanger method involves first separating the two strands

of DNA and then adding chemically altered forms of the adenine, cytosine, guanine, and thymine bases. The altered bases stop the process of DNA replication as they are added to the strand of DNA, resulting in a series of short pieces of DNA. These short pieces are placed in order from shortest to longest in order to read the entire original sequence of DNA.

SARCOIDOSIS. A chronic disease characterized by nodules forming in the lymph nodes, lungs, bones, and skin.

SARCOMERES. The basic functional units of striated muscle tissue. Sarcomeres consist of fibrous proteins that slide past each other as the muscle contracts and relaxes.

SARCOPLASMIC RETICULUM. A system of tiny tubes located inside muscle cells that allow muscles to contract and relax by alternatively releasing and storing calcium.

SATELLITES. Small segments of genetic material at the tips of the short arms of chromosomes 13, 14, 15, 21, and 22.

SAVANTS. People with ASD who have unusual abilities in areas such as art, math, or music.

SCAPHOCEPHALY. An abnormally long and narrow skull.

SCAPULA. Shoulder blade.

SCAPULAR WINGING. The jutting-back of the shoulder blades that can be caused by muscle weakness.

SCHIZENCEPHALY. A rare disorder caused by abnormal slits within the brain.

SCHIZOPHRENIA. A psychotic disorder characterized by loss of contact with one's environment, deterioration of everyday functioning, and personality disintegration.

SCHWANNOMA. A tumor that grows from the cells that line the nerves of the body (Schwann cells).

SCINTIGRAPHY. Injection and detection of radioactive substances to create images of body parts.

SCLERA. The tough white membrane that forms the outer layer of the eyeball.

SCLERODERMA. A relatively rare autoimmune disease affecting blood vessels and connective tissue that makes skin appear thickened.

SCLEROSIS. Hardening.

SCOLIOMETER. A tool for measuring trunk asymmetry; it includes a bubble level and angle measure.

SCOLIOSIS. An abnormal, curvature of the spine. In this condition, the curvature is usually side to side.

SCRAPIE. A fatal disease of sheep and goats that is classified as a transmissible spongiform encephalopathy. Although scrapie is caused by a prion, it is not transmissible to humans.

SCREENING. Process through which carriers of a trait may be identified within a population.

SCROTUM. The sac of skin that holds the testicles.

SEASONAL AFFECTIVE DISORDER (SAD). A subset of depressive disorder in which the person experiences depressive symptoms in the winter (or summer) but feels consistent the rest of the year. SAD is also called the winter blues, summertime sadness, or seasonal depression.

SEBACEOUS. Related to the glands of the skin that produce an oily substance.

SEBASTIAN SYNDROME. A subgroup of the *MYH9*-related disorders characterized by the platelet disorder and inclusion bodies in the white blood cells.

SECOND-DEGREE RELATIVE. Two relatives (grandmother/father and grandchild or aunt/uncle and niece/nephew) who share 25% of their genes in common.

SECONDARY CRANIOSYNOSTOSIS. Abnormal closure of the cranial sutures caused by a failure of the brain to grow and expand.

SECONDARY FINDINGS. Incidental or unanticipated findings, often of a previously unsuspected disease risk, resulting from the use of WES or WGS.

SEDATIVE. Medication that has a soothing or tranquilizing effect.

SEIZURES. An abnormal electrical discharge from the brain that usually results in convulsion of the body.

SEMEN. A whitish, opaque fluid that is released at ejaculation and contains sperm.

SEMINAL FLUID. Semen without sperm.

SEMINAL VESICLES. The pouches above the prostate that store semen.

SENSITIVITY. The proportion of people with a disease who are correctly diagnosed (test positive based on diagnostic criteria). The higher the sensitivity of a test or diagnostic criteria, the lower the rate of "false negatives," people who have a disease but are not identified through the test.

SENSORINEURAL HEARING LOSS (SNHL). Hearing loss that occurs when parts of the inner ear, such as the cochlea and/or auditory nerve, do not work correctly. It is often defined as mild, moderate, severe, or profound,

depending upon how much sound can be heard by the affected individual.

SENSORY NEURONS. Class of neurons that specifically regulate and control external stimuli (e.g., sight, sound).

SEPSIS. An infection of the bloodstream.

SEPTAL. Relating to the septum, the thin muscle wall dividing the right and left sides of the heart. Holes in the septum are called septal defects.

SEPTAL DEFECT. A hole in the heart.

SEPTUM. In anatomy, a wall of tissue that divides a body cavity or structure into smaller sections. The intraventricular septum is the tissue that divides the two lower chambers of the heart.

SEPTUM PELLUCIDUM. A membrane between two of the normal cavities of the brain that prevents electrical signals from passing between different portions of the brain.

SEQUENCE. As a noun, it is the exact order of bases in a nucleic acid or of amino acids in a protein; as a verb it means to determine the sequence of chemical constituents in an amino acid or the bases in a strand of DNA.

SERIAL CASTING. A series of casts designed to gradually move a limb into a more functional position.

SEROLOGICAL. Pertaining to serology, the science of testing blood to detect the absence or presence of antibodies (an immune response) to a particular antigen (foreign substance).

SEROSITIS. Inflammation of a serosal membrane. Polyserositis refers to the inflammation of two or more serosal membranes.

SEROTONIN. A neurotransmitter that transmits signals between nerve cells; low levels are associated with depression and PTSD.

SEROTONIN DOPAMINE ANTAGONISTS (SDAS). The newer second-generation antipsychotic drugs, also called atypical antipsychotics, including clozapine (Clozaril), risperidone (Risperdal), and olanzapine (Zyprexa).

SEROTYPE. One form of a bacteria that has unique surface proteins. Each serotype causes a unique antibody response from a person's immune system.

SERUM. The liquid part of blood.

SERUM CK TEST. A blood test that determines the amount of the enzyme creatine kinase (CK) in the blood serum. An elevated level of CK in the blood indicates

that muscular degeneration has occurred and/or is occurring.

SERUM CREATININE. A chemical in the urine of kidney patients used to determine kidney disease and failure. Elevated levels of serum creatinine are an early marker for severe kidney disease or failure.

SEVERE COMBINED IMMUNODEFICIENCY (SCID). A group of rare, life-threatening diseases present at birth that cause a child to have little or no immune system. As a result, the child's body is unable to fight infections.

SEX CHROMOSOMES. The X and Y chromosomes that determine the sex of the individual.

SEX-LINKED. A gene located on, and thus a trait linked to, the X or Y chromosomes.

SHAGREEN PATCH. Area of tough and dimpled skin.

SHOCK. An inability to provide the body with the oxygen it requires, sometimes due to large amounts of bleeding or fluid loss.

SHORT RIB POLYDACTYLY SYNDROMES. A collection of genetic disorders characterized by abnormally short ribs and extra fingers or toes. Research is ongoing to determine if these disorders are the result of mutations in a common gene.

SHORT STATURE. Height of less than three standard deviations from the mean for age, race, and gender. Shorter than normal height, can include dwarfism.

SHORT TRUNK. An abnormally short torso or body.

SHUNT. A small tube placed in a ventricle of the brain to direct cerebrospinal fluid away from the blockage into another part of the body.

SIALIC ACID. N-acetylneuraminic acid, a sugar that is often at the end of an oligosaccharide on a glycoprotein.

SIALIDOSIS. An inherited disorder also known as neuraminidase deficiency.

SICKLE CELL. A red blood cell that has assumed an elongated shape due to the presence of hemoglobin S.

SICKLE-CELL DISEASE. A chronic, inherited blood disorder characterized by sickle-shaped red blood cells. It occurs primarily in people of African descent and produces symptoms including episodic pain in the joints, fever, leg ulcers, and jaundice.

SIDEROBLAST. An abnormal erythroblast that contains a cell nucleus with iron granules accumulated in mitochondria around the nucleus.

SIGMOIDOSCOPY. Examination of the rectum and lower colon with a flexible instrument passed through the

anus; also used to remove polyps and obtain biopsy samples.

SIGN. An indication of disease, injury, or other physical problem that can be observed by someone other than the person experiencing these conditions.

SILVER SYNDROME. An alternative term for Russell-Silver syndrome. Many doctors use this term to mean an individual with Russell-Silver syndrome who also has body asymmetry.

SINGLE-NUCLEOTIDE POLYMORPHISM (SNP). A DNA sequence variation in which a single nucleotide in the genome differs between two individuals of the same species or between two paired chromosomes. SNPs affect individuals' susceptibility to diseases.

SINGLE-PHOTON COMPUTED TOMOGRAPHY (SPECT). Nuclear imaging that uses gamma rays to produce 3D images of inside the body.

SIRENOMELIA. An extremely rare birth defect, also known as mermaid syndrome, in which affected infants are born with a single lower extremity or with two legs that are fused together.

SISTER-CHROMATID EXCHANGE (SCE). Exchange of DNA between sister chromatids during DNA replication; excessive SCE can cause the gaps, breaks, and structural rearrangements of chromosomes that are diagnostic of Bloom syndrome.

SITUS SOLITUS. Normal organ placement in the body with the heart, stomach, and spleen placed toward the left, and the liver and gallbladder on the right.

SJÖGREN'S SYNDROME. A chronic inflammatory disease often associated with rheumatoid arthritis.

SKELETAL DYSPLASIA. A group of syndromes consisting of abnormal prenatal bone development and growth.

SKELETAL MUSCLE. A muscle under voluntary control that attaches to bone and controls movement.

SKEWED INACTIVATION. Random inactivation of either the paternally or maternally derived X chromosome in the female; also called lyonization, and occurs early in embryonic development.

SKIN ERYTHEMA. Irregular red streaks of skin.

SKIN HEMATOMA. Blood from a broken blood vessel that has accumulated under the skin.

SLEEP APNEA. A potentially life-threatening condition in which the individual has episodes during sleep in which breathing temporarily stops.

SLEEP PARALYSIS. An abnormal episode of sleep in which the patient cannot move for a few minutes, usually occurring on falling asleep or waking up. Often found in patients with narcolepsy.

SLY DISEASE. Also called Sly syndrome, an autosomal recessive lysosomal storage disease caused by a mutation in a gene on chromosome 7. It is named for William Sly, the American biochemist who discovered it.

SMALL INTESTINE. The part of the digestive tract in between the stomach and the large intestine.

SMALL TESTES. Refers to the size of the male reproductive glands, located in the cavity of the scrotum.

SMOOTH MUSCLE CELLS (SMCS). The layered cells in the wall of the aorta and other arteries.

SNEDDON SYNDROME. Adenosine deaminase 2 deficiency that may be caused by mutations in the *CECRI* gene, with symptoms usually developing later than those of polyarteritis nodosa.

SOCIAL DETERMINANTS OF HEALTH. Conditions in the places where people live, learn, work, and play that affect a wide range of health and quality-of-life issue for individuals and groups.

SOMATIC. Relating to the nonreproductive parts of the body.

SOMATIC CELLS. All the cells of the body except for the egg and sperm cells.

SOMATIC MUTATION. Sporadic mutation; a gene mutation that is not inherited from a parent carrying the mutation but rather occurs in an egg or sperm cell or during fetal development.

SOMATOSTATIN. A body chemical, known as a cyclic peptide, involved in the release of human growth hormone from the pituitary gland.

SORE. An open wound or a bruise or lesion on the skin.

SPASMODIC TORTICOLLIS. A painful chronic neurological disorder in which involuntary contractions of the neck muscles cause the person's head to twist or turn from side to side or upward and downward. It is also called cervical dystonia.

SPASTIC PARAPLEGIA. Inability to walk, due to lack of proper neural control over the leg muscles.

SPASTIC QUADRIPARESIS. Muscle spasms involve both the legs and the arms.

SPASTICITY. Increased muscle tone or stiffness that leads to uncontrolled, awkward movements.

SPASTIN. A protein encoded by the *SPAST* gene that regulates the length of microtubules and dissolves microtubule structures that are no longer needed.

SPAWNING. The process of releasing both eggs and sperm into water by fish and other aquatic animals.

SPECIFICITY. The proportion of people without a disease who are correctly classified as healthy or not having the disease (test negative based on diagnostic criteria). The higher the specificity of a test or diagnostic criteria, the lower the number of “false positives,” people who don’t have a disease but who “test” positive.

SPEECH THERAPIST. Person who specializes in teaching simple exercises to improve speech.

SPHEROCYTE. A red blood cell that has an abnormal spherical shape rather than the normal shape of a concave disk.

SPHINGOMYELIN. A group of sphingolipids containing phosphorus.

SPHINGOMYELINASE. An enzyme needed to break down sphingomyelin into ceramide.

SPHYGMOMANOMETER. An inflatable cuff used to measure blood pressure.

SPINA BIFIDA. A birth defect in which there is incomplete closure of the spine and the meninges (membranes) over the spinal cord.

SPINA BIFIDA OCCULTA. The failure of vertebrae to close into the neural tube without nerves protruding. This is most often asymptomatic.

SPINDLE APPARATUS. A network of microtubules (also known as spindle fibers) that forms during cell division to pull chromosomes during metaphase to the poles of the cell. The microtubules are formed from a protein called tubulin.

SPINOCEREBELLAR ATAXIA, AUTOSOMAL RECESSIVE 14 (SCAR14). Spectrin-associated autosomal recessive cerebellar ataxia type 1 (SPARCA1).

SPITZ NEVUS. A benign reddish or reddish-brown skin lesion that is difficult to distinguish from melanoma and is usually removed for that reason. Spitz nevi are named for Sophie Spitz, an American pathologist who first described them in 1948.

SPLAY. Turned outward or spread apart.

SPLEEN. An organ located in the upper abdominal cavity that filters out old red blood cells and helps fight bacterial infections. It is responsible for breaking down spherocytes at a rapid rate.

SPLENECTOMY. Removal of the spleen.

SPLENIC FLEXURE. The area of the large intestine at which the transverse colon meets the descending colon.

SPLENOMEGALY. Abnormal enlargement of the spleen.

SPONDYLOARTHRITIS (SPONDYLITIS). Inflammatory disease of the joints of the spine.

SPONDYLOEPIPHYSEAL DYSPLASIA. Abnormality of the vertebra and epiphyseal centers that causes a short trunk.

SPONDYLOEPIPHYSEAL DYSPLASIA CONGENITA. A subtype of collagenopathy, types II and IX, with symptoms that are similar to but milder than those of hypochondrogenesis and achondrogenesis type II.

SPONDYLOSIS. Arthritis of the spine.

SPONTANEOUS. Occurring by chance.

SPOON HAND. A type of syndactyly in which the thumb is joined to the four fingers as well as the fingers being fused together. It is also known as “mitten hand.”

SPORADIC. Describes genetic diseases that develop in patients with no family history of the disease.

SPORADIC CANCER. A cancer that occurs at random in the population with no known cause.

SPORADIC INHERITANCE. A situation in which a gene mutates spontaneously, or for the first time, to cause the disorder in a person with no family history of the disorder.

SPORADIC RETINOBLASTOMA. A type of retinoblastoma where the cancer-causing gene variants happen in a retinal cell after birth and are not inherited.

SPUTUM. A mixture of saliva and mucus from the lungs.

STAGE. The extent of a tumor’s progress. Tests are done to determine whether a tumor is localized to an organ or whether it has spread to the lymph nodes and/or other organs. Treatment is determined by the stage of the cancer.

STAGING. A method of describing the degree and location of cancer.

STATIC ENCEPHALOPATHY. A disease of the brain that does not get better or worse.

STATUS EPILEPTICUS. A potentially life-threatening seizure that either lasts longer than five minutes or consists of two seizures within a five-minute period.

without the patient returning to normal consciousness between the seizures.

STELLATE. A star-like, lacy white pattern in the iris. Most often seen in light-eyed individuals.

STEM CELLS. Cells that can transform into any different type of cell and can make copies of themselves indefinitely.

STENOSIS. The constricting or narrowing of an opening or passageway.

STENT. A tubular device made of metal or plastic that is inserted into a body duct or tube to prevent collapse, blockage, or overgrowth.

STEREOTYPY. A repetitive movement, gesture, or utterance; examples include head banging, rocking, or repeatedly crossing and uncrossing the legs. Stereotypy is found in persons with intellectual disabilities and some forms of schizophrenia as well as autism spectrum disorders.

STERILITY. The inability of either a male or a female to produce offspring. Sterility may result from physical injury, disease, genetic disorders, or exposure to radiation.

STILLBIRTH. The birth of a baby who has died sometime during the pregnancy or delivery.

STOMACH. The organ that holds and begins digestion of food.

STRABISMUS. An improper muscle balance of the ocular muscles resulting in crossed or divergent eyes.

STRATUM CORNEUM. The outer portion of the epidermis made up primarily of dead, flattened cells filled with the protein keratin.

STRICTUREPLASTY. A surgical procedure in which a narrowed portion of the intestine is removed and the remaining section is reconnected to a healthy section of bowel.

STROKE. An obstruction (ischemic) or rupture (hemorrhagic) of a blood vessel in the brain, causing death of brain tissue and potentially affecting physical and mental functioning.

STROMA. Middle layer of the cornea, representing about 90% of the entire cornea.

STRUCTURAL VARIATIONS. Variations in the structure of an organism's chromosome that are larger than single-nucleotide polymorphisms but smaller than a chromosome abnormality. Structural variations can include deletions, duplications, and insertions as well as copy number variations. Many structural variations are linked to genetic diseases but many more are not.

SUBARACHNOID SPACE. The space between two membranes surrounding the brain, the arachnoid and pia mater.

SUBCORTICAL BAND HETEROTOPIA. A mild form of lissencephaly type 1 in which abnormal bands of gray and white matter are present beneath the cortex near the ventricles.

SUBCORTICAL INFARCTS. Obstruction of nerve centers below the cerebral cortex of the brain.

SUBPENDYMAL GIANT CELL ASTROCYTOMA. Benign (noncancerous) tumor of the brain comprised of star-shaped cells (astrocytes).

SUBPENDYMAL NODULE. Growth found underneath the lining of the ventricles in the brain.

SUBMETACENTRIC. A centromere located between the center and the top of the chromosome.

SUBSTANTIA NIGRA. One of the movement control centers of the brain.

SUBSTRATE. A compound on which an enzyme works in a biochemical reaction.

SUBTELOMERE. The section of a chromosome immediately next to the telomere at the end of the chromosome.

SUDDEN CARDIAC DEATH (SCD). A term used to describe an unexpected death due to cardiac causes that occurs within an hour of symptom onset in a person with known or unknown heart disease.

SUDDEN INFANT DEATH SYNDROME (SIDS). The unexpected, sudden death of a child under one year of age. Often called "crib death."

SUDDEN UNEXPLAINED DEATH IN EPILEPSY (SUDEP). A fatal complication of epilepsy that accounts for about 15% of deaths in epilepsy patients. It is thought to result from a combination of factors, including cardiac and respiratory as well as neurological factors.

SULFATE. A chemical compound containing sulfur and oxygen.

SURROGACY. The practice in which a woman, called a surrogate mother, carries a pregnancy to term for another person or persons who cannot have children, who will become the legal parent(s) of the child after birth. Surrogacy may or may not involve a legal contract.

SUTURE. A "seam" that joins two surfaces together.

SYMPHALANGISM. Fusion of phalanges at their ends.

SYMPTOM. An indication of disease, injury, or other physical problem reported by the person experiencing these conditions, not by an outside observer.

SYNCHRONOUS. Occurring simultaneously.

SYNCOPE. A brief loss of consciousness caused by insufficient blood flow to the brain.

SYNDACTYLY. A birth defect in which the fingers or toes are joined either by webs of soft tissue (simple syndactyly) or by fusion of the bones (complex syndactyly). Syndactyly may occur either as an isolated birth defect or as part of a genetic syndrome like CLSS.

SYNDROME. A group of signs and symptoms that collectively characterize a disease or disorder.

SYNDROMIC AUTISM. A term used to describe autism that exists in combination with other clinical features, including physical as well as developmental abnormalities.

SYNDROMIC HEARING LOSS. Hearing loss that occurs as part of an underlying genetic syndrome.

SYNKINESIA. Involuntary movement of a part of the body when another part of the body moves.

SYNOPHRYS. A feature in which the eyebrows join in the middle; also called blepharophimosis.

SYNOSTOSIS (PLURAL, SYNOSTOSES). The medical term for the fusion of two bones.

SYNOVITIS. Inflammation of the synovium, a membrane found inside joints.

SYRINGOMYELIA. Excess fluid in the spinal cord.

SYSTEMIC LUPUS ERYTHEMATOSUS (SLE). A chronic, inflammatory autoimmune disorder that is the most common type of lupus.

SYSTEMIC RACISM. Also known as institutional racism, this is racism written into the laws, regulations, and practices of institutions, organizations, and groups. Systemic racism results in discrimination in education, housing, employment, health care, the criminal justice system and other aspects of life.

SYSTEMIC SCLEROSIS. A rare disorder that causes thickening and scarring of multiple organ systems.

SYSTOLE. The rhythmic contraction of the heart, particularly of the ventricles, in which blood is pumped through the aorta and the pulmonary artery.

SYSTOLIC BLOOD PRESSURE. Blood pressure when the heart contracts (beats).

T

T CELLS. White blood cells that fight both virally and bacterially infected cells within the body.

TACHYCARDIA. An abnormally rapid heartbeat in an adult at rest (that is, not exercising), usually regarded as 100 beats per minute or faster.

TAFAZZIN GENE (TAZ). A human gene located on the X chromosome that encodes tafazzin, a protein expressed at high levels in cardiac and skeletal muscle. Mutations in this gene have been associated with a number of disorders, including 3-methylglutaconic aciduria type 2 and dilated cardiomyopathy.

TAI-CHI. A Chinese system of physical exercises that uses slow, smooth body movements to help with posture control and relaxation.

TALIPES EQUINOVARUS. A type of clubfoot characterized by a downward and inward pointing foot.

TARGETED CARRIER TESTING. Testing to see if a person is a carrier of only one or a few conditions that the person is at risk for based on personal or family history or ancestry.

TARGETED THERAPY. A type of drug or other substance that identifies and attacks specific types of cancer cells with less damage to normal cells. Most targeted therapy drugs are either monoclonal antibodies or small-molecule drugs.

TAU. A protein involved in maintaining the internal structure of nerve cells; tau is damaged in Alzheimer's disease and forms neurofibrillary tangles.

TAY-SACHS DISEASE. An inherited biochemical disease caused by lack of a specific enzyme in the body. In classical Tay-Sachs disease, previously normal children become blind and mentally handicapped, develop seizures, and decline rapidly. Death often occurs between the ages of three and five years. Tay-Sachs disease is more common among individuals of eastern European Jewish background, but it has been reported in other ethnic groups as well.

TCA CYCLE. Formerly known as the Krebs cycle, this is the process by which glucose and other chemicals are broken down into forms that are directly useable as energy in the cells.

TELANGIECTASIS. Very small arteriovenous malformations or connections between the arteries and veins. The result is red spots on the skin known colloquially as "spider veins."

TELANGIECTATIC ERYTHEMA. A localized collection of dilated blood capillaries near the surface of the skin; congenital telangiectatic erythema is another name for Bloom syndrome.

TELOGEN. The resting phase of the hair growth cycle.

TELOMERE. A region of repeated DNA sequences at each end of a chromosome that serves to stabilize the chromosome. Telomeres are progressively shortened each time the cell divides until cell division stops, usually around 50 divisions. HeLa cells are distinctive in that their telomeres are copied repeatedly during cell division, so that they are never shortened.

TEMPORAL LOBE. Region of the brain located at the bottom middle part of cortex, right behind the temples; it is responsible for processing auditory information.

TENDON. A strong connective tissue that connects muscle to bone.

TENDON REFLEX. Reflex contraction of the muscle that is observed by tapping on its tendon.

TENOTOMY. A surgical procedure that cuts the tendon of a contracted muscle to allow lengthening.

TERATOGEN. Any drug, chemical, maternal disease, or exposure that can cause physical or functional defects in an exposed embryo or fetus.

TERATOGENIC. Describes any agent that can cause birth defects or intellectual disability in a developing fetus. Common teratogens are medications or other chemicals, but they also include infections, radiation, maternal medical condition, and other agents.

TERATOZOOSPERMIA. A condition in which at least 85% of sperm are abnormal; caused by mutations in several different genes.

TERMINAL DELETION. The abnormal early termination of a chromosome caused by the deletion of one of its ends.

TESTES. The male reproductive organs that produce male reproductive cells (sperm) and male hormones.

TESTICLES. The testes and their enclosing structures.

TESTOSTERONE. Hormone produced in the testicles that is involved in male secondary sex characteristics.

TETRALOGY OF FALLOT. A congenital heart defect consisting of four (tetralogy) associated abnormalities: ventricular septal defect (VSD—hole in the wall separating the right and left ventricles); pulmonic stenosis (obstructed blood flow to the lungs); the aorta “overrides” the ventricular septal defect; and thickening (hypertrophy) of the right ventricle.

TETRAMER. Protein that consists of four amino acid chains.

TETRAPARESIS. Muscle weakness affecting all four limbs.

TETRAPHOCOMELIA. Absence of all, or a portion of, all four limbs. The hands or feet may be attached directly to the trunk.

TETRAPLEGIA. Paralysis of all four limbs. Also called quadriplegia.

TETRASOMY. Refers to the presence of four parts or copies of a chromosome or part of a chromosome.

THALAMUS. A pair of large egg-shaped structures near the brain stem that act as the main sensory relay station and help with control of movement.

THALIDOMIDE. A mild sedative that is teratogenic, causing limb, neurologic, and other birth defects in infants exposed during pregnancy. Women used thalidomide (early in pregnancy) in Europe and in other countries between 1957 and 1961. It is still available in many places, including the United States, for specific medical uses (leprosy, AIDS, cancer).

THERMOLABILE. Heat-sensitive. A thermolabile protein is a protein that easily loses its shape when heated even only slightly.

THIRD-PARTY INTERPRETATION (TPI) SERVICE. An online tool that analyzes the raw DNA data from a DTC genetic test and provides a genetic health risk report.

THIRD-PARTY REPRODUCTION. Any instance of human reproduction in which DNA or gestation is provided by a third-party donor other than the parent(s) who will rear the resulting child. It is also called donor-assisted reproduction.

THORACIC CAVITY. The chest.

THORACOPAGUS. Conjoined twins joined at the upper body who share a heart.

THORAX. Chest cavity.

THREE-PARENT BABY. A term used in the mass media to describe a baby produced from the genetic material of one man and two women through the use of mitochondrial replacement technologies and three-person in vitro fertilization (IVF). It is not a scientific term.

THROMBOCYTOPENIA. A persistent decrease in the number of blood platelets usually associated with hemorrhaging.

THROMBOEMBOLISM. A condition in which a blood vessel is blocked by a free-floating blood clot carried in the bloodstream.

THROMBOPHILIA. A disorder in which there is a greater tendency for thrombosis (clot in blood vessel).

THROMBOPHLEBITIS. Inflammation of veins due to blood clots.

THROUGHPUT. In general, the rate at which data can be processed, or the work that a computer can do in a specific period of time. High-throughput sequencing refers to any of a set of technologies that can produce large numbers of DNA sequences concurrently.

THYMUS GLAND. An endocrine gland located in the front of the neck that houses and transports T cells, which are part of the immune system and help to fight infection.

THYROID GLAND. A gland located in the front of the neck that is responsible for normal body growth and metabolism. The thyroid traps a nutrient called iodine and uses it to make thyroid hormones, which allow for the breakdown of nutrients needed for growth, development, and body maintenance.

THYROID-STIMULATING HORMONE (TSH). A hormone produced in the anterior lobe of the pituitary gland that stimulates the thyroid gland to produce thyroxine and triiodothyronine. It is also known as thyrotropin.

THYROTROPIN-RELEASING HORMONE (TRH). A hormone produced by the hypothalamus that stimulates the pituitary gland to release TSH.

THYROXINE (T4). The major form of thyroid hormone circulating in the blood. It is converted in the liver and the thyroid gland itself into triiodothyronine, the most active thyroid hormone.

TIBIALIS. Muscles of the calf.

TIC. Brief and intermittent involuntary movement or sound.

TISSUE. A group of cells that have a common function. The four types of tissue are: connective, epithelial (skin), muscle, and nervous tissue.

TITUBATION. Tremor of the head.

tone. A term used to describe the tension of muscles. Increased tone is increased tension in the muscles.

TONOMETER. A device used to measure fluid pressures in the eye.

TORSADE DE POINTES. A type of tachycardia of the ventricles characteristic of Jervell and Lange-Nielsen syndrome.

TORTICOLLIS. Twisting of the neck to one side that results in abnormal carriage of the head and is usually caused by muscle spasms. Also called wry neck.

TOXEMIA OF PREGNANCY. A condition characterized by high blood pressure and large amounts of protein in the urine. It is also called pre-eclampsia. If left untreated, it may result in the breakdown of red blood cells, liver and kidney dysfunction, and seizures.

TOXIC. Poisonous.

TRABECULAR MESHWORK. A sponge-like tissue that drains the aqueous humor from the eye.

TRACHEA. The long tube connecting from the larynx down into the lungs, responsible for passing air.

TRACHEO-ESOPHAGEAL FISTULA. Abnormal connection between the trachea and esophagus, frequently associated with the esophagus ending in a blind pouch.

TRACHEOSTOMY. An opening surgically created in the trachea (windpipe) through the neck to improve breathing.

TRACTION ALOPECIA. Hair loss caused by pressure or tension on the scalp related to certain types of hair styles or equipment worn on the head.

TRAIT. In genetics, a specific characteristic of an individual organism, such as height, weight, or blood type. Traits are determined both by genes and the interaction of the environment with genes.

TRANSABDOMINAL CVS. Chorionic villus sampling performed using a needle inserted through the abdomen.

TRANSCERVICAL CVS. Chorionic villus sampling performed using a catheter inserted through the vagina and cervix.

TRANSCRIPTION. The process by which DNA is changed into RNA.

TRANSCRIPTION FACTOR. A protein that binds to specific DNA sequences and controls the rate of transcription of genetic information from DNA to messenger RNA.

TRANSCRIPTIONAL REPRESSION. Methods that inhibit transcription such as protein binding to promoters to impede binding of RNA polymerase.

TRANSFER RNA (TRNA). A small RNA molecule that binds to a complementary mRNA sequence and then attaches the corresponding amino acid to the protein chain.

TRANSFERRIN. An iron-binding glycoprotein found in blood plasma that controls the level of iron in biological fluids. The serum transferrin level can be used to check for iron deficiency and hemochromatosis.

TRANSFUSION. The injection of a component of the blood from a healthy person into the circulation of a person who is lacking or deficient in that same component of the blood.

TRANSGENIC. Referring to an organism in which one or more sequences of DNA from another species have been introduced by artificial means. Animals are typically made transgenic by having a small segment of the other species' DNA injected into an egg or developing embryo.

TRANSIENT ISCHEMIC ATTACK (TIA). A neurologic dysfunction that comes and goes quickly and is similar to a stroke.

TRANSILLUMINATION. A diagnostic technique that involves shining a strong light through body tissues in order to detect defects. Transillumination of the iris may be used to diagnose congenital microcoria.

TRANSITION MUTATION. A point mutation where an (A) and (G) base are switched or a (C) and (T) base are switched.

TRANSLATION. The process of converting the sequence of messenger RNA into a series of amino acids in order to implement the genetic code of an organism.

TRANSLOCATION. The transfer of one part of a chromosome to another chromosome during cell division, which can create oncogenes, amplify oncogenes, or inactivate a tumor-suppressor gene.

TRANSPLANTATION. The implanting of an organ from either a deceased person (cadaver) or from a live donor to a person whose organ has failed.

TRANSPOSITION OF THE GREAT ARTERIES (TGA). A reversal of the two great arteries of the heart, causing oxygenated blood to be carried back to the lungs and deoxygenated blood to be transported throughout the body.

TRANSRECTAL ULTRASOUND. A procedure in which a probe is placed in the rectum. High-frequency sound waves that cannot be heard by humans are sent out from the probe and reflected by the prostate. These sound waves produce a pattern of echoes that are then used by the computer to create sonograms or pictures of areas inside the body.

TRANSVAGINAL ULTRASOUND. A way to view the ovaries by using sound waves. A probe is inserted into the vagina, and the ovaries can be seen. Color doppler

imaging measures the amount of blood flow, as tumors sometimes have high levels of blood flow.

TRANSVERSION. A genetic term referring to a specific substitution of one base pair for another. There are only four possible transversions: guanine for cytosine, cytosine for guanine, adenine for thymine, or thymine for adenine.

TRANSVERSION MUTATION. A point mutation where an (A or G) base is changed to a (T or C) or vice versa.

TRAUMA. Injury.

TREMOR. Involuntary rhythmic back-and-forth movements involving one or more parts of the body. Tremor is most commonly seen in the hands but can affect almost any part of the body.

TRICHOTILLOMANIA. A psychiatric disorder characterized by hair loss resulting from compulsive pulling or tugging on one's hair.

TRIGGER DRUGS. Specific drugs used for muscle relaxation and anesthesia that can trigger an episode of malignant hyperthermia in a susceptible person. The trigger drugs include halothane, enflurane, isoflurane, sevoflurane, desflurane, methoxyflurane, ether, and succinylcholine.

TRIGLYCERIDE. A type of lipid consisting of a molecule of glycerol and three fatty acid fragments.

TRIGONOCEPHALY. An abnormal development of the skull characterized by a triangle-shaped forehead.

TRIIODOTHYRONINE (T3). The most active and final form of thyroid hormone.

TRIMESTER. A three-month period. Human pregnancies are normally divided into three trimesters: first (conception to week 12), second (week 13 to week 24), and third (week 25 until delivery).

TRINUCLEOTIDE REPEAT EXPANSION. A sequence of three nucleotides that is repeated too many times in a gene sequence.

TRIOSE PHOSPHATE ISOMERASE. Abbreviated TPI, this is the enzyme responsible for the conversion of dihydroxyacetone phosphate (DHAP) into D-glyceraldehyde-3-phosphate (GAP). DHAP and GAP are the two major products of a step in the multi-step process that converts glucose into ATP to supply the body with the energy it needs to sustain itself. Only GAP can continue in this process, but DHAP is produced in much higher quantities. People with TPI deficiency cannot change DHAP into GAP as efficiently as unaffected people, resulting in insufficient amounts of ATP from glucose to maintain normal cell function.

TRIPHALANGEAL THUMB (TPT). A thumb that has three bones rather than two.

TRIPLOID. Three sets of chromosomes; in humans, this is 69 chromosomes.

TRISOMY. A type of aneuploidy in which there are three copies of a specific chromosome in cells instead of the normal two. Genetic disorders caused by trisomies include Down syndrome (trisomy 21) and Edwards syndrome (trisomy 18).

TRUNCUS ARTERIOSUS. A condition in which a structure present during fetal development fails to develop normally into two separate structures, the aorta and the pulmonary trunk. Thus there is only one arterial trunk structure leading from the heart instead of two. Often there is a ventricular septal defect (VSD) present.

TRYPSIN. A digestive enzyme found in pancreatic fluid that breaks down proteins. This enzyme is abnormal in hereditary pancreatitis.

TRYPTOPHAN. A crystalline amino acid widely distributed in proteins and essential to human life.

TUBEROUS SCLEROSIS. A genetic disorder of the skin and nervous system involving the formation of small tumors in various organs and sometimes causing ASD.

TUBULE. A small tube lined with glandular epithelium in the kidney.

TUMOR. An abnormal growth of cells. A tumor may be benign (noncancerous) or malignant (cancerous).

TUMOR-EDUCATED PLATELETS (TEPS). Platelets that have had their RNA profiles changed through association with cancerous tumors.

TUMOR NECROSIS FACTOR (TNF). A protein called a cytokine that mediates inflammation throughout the body and activates immune system cells; targeted by biologics for treating colitis.

TUMOR-SUPPRESSOR GENES. Genes that normally help prevent cancer from developing in a cell. Variants (mutations) in tumor suppressor genes make the cell more likely to become cancerous.

TURNER SYNDROME. A chromosomal disorder with a 45,X or 45,X0 karyotype that affects only females, in which one of the X chromosomes is either partially or completely missing. Most women with Turner syndrome are infertile because of a lack of ovarian function.

TYMPANOPLASTY. Any of several operations on the eardrum or small bones of the middle ear to restore or improve hearing in patients with conductive hearing loss.

TYPE 1 DIABETES MELLITUS (T1D). An autoimmune disorder that generally develops in childhood in which the immune system attacks and destroys insulin-producing beta cells; also called insulin-dependent diabetes mellitus (IDDM).

TYPE 2 DIABETES MELLITUS (T2D). A condition in which the body does not properly utilize glucose due to insulin resistance or decreased insulin production; also called non-insulin-dependent diabetes mellitus (NIDDM).

TYPE I INCONTINENTIA PIGMENTI. Sporadic IP. This disorder is caused by mutations in the gene at Xp11. These mutations are not inherited from the parents, they are de novo mutations. This type of IP probably represents a different disease than type II IP.

TYPE II INCONTINENTIA PIGMENTI. Familial, male-lethal type IP. This type of IP is the “classic” case of IP. It is caused by mutations in the NEMO gene located at Xq28. Inheritance is sex-linked recessive.

TYPE XI COLLAGEN. A type of collagen that produces an organic gel that helps cartilage to convert into bone and helps bone growth in the developing fetus.

TYROSINE (TYR). The amino-acid precursor of melanin.

U

UBIQUITIN-PROTEASOME SYSTEM. A multicomponent system that identifies and degrades unwanted proteins in the cytoplasm of all cells. It is involved in cell growth and differentiation, DNA replication and repair, apoptosis, and stress and immune responses.

ULCER. Inflammatory lesion of the mucous-like tissue in the stomach.

ULCERATIVE COLITIS (UC). A form of colitis characterized by ulcers in the colon that may bleed and produce pus.

ULNA. One of the two bones of the forearm, the one opposite the thumb.

ULTRASONOGRAPH. The image produced by the use of inaudible sound of high frequency called ultrasound to photograph a tissue, organ, or infant.

ULTRASOUND. An imaging technique that uses high-frequency sound waves to help display internal structures in the body.

UMBILICAL HERNIA. Protrusion of the bowels through the abdominal wall, underneath the navel.

UNDESCENDED TESTICLES. Testicles that failed to move from the abdomen to the scrotum during the development of the fetus.

UNILATERAL. Refers to one side of the body or only one organ in a pair.

UNIPARENTAL DISOMY (UPD). An unusual genetic status in an individual in which one parent is the source of both chromosomes of a pair.

UPSHOOT. Upward movement of the eye.

UREA. A nitrogen-containing compound that can be excreted through the kidney.

UREA CYCLE. A series of complex biochemical reactions that remove nitrogen from the blood so ammonia does not accumulate.

UREA CYCLE DISORDER. A disease caused by a lack of an enzyme that cleans the blood of ammonia.

UREMIC POISONING. Accumulation of waste products in the body.

URETERS. Tubes through which urine is transported from the kidneys to the bladder.

URETHRA. The tubular portion of the urinary tract connecting the bladder and external meatus through which urine passes. In males, seminal fluid and sperm also pass through the urethra.

URETHRAL ATRESIA. Abnormal closure of the tube that leads from the bladder to the outside of the body.

URETHRITIS. Inflammation of the urethra.

URINARY URGENCY. An exaggerated or increased sense of needing to urinate.

URTICARIA. Also known as hives. Usually associated with an allergic reaction.

USHER SYNDROME. The most common type of autosomal recessive syndromic hearing loss.

UTERUS. A muscular, hollow organ of the female reproductive tract. The uterus contains and nourishes the embryo and fetus from the time the fertilized egg is implanted until birth.

UVEA. The medical term for the pigmented middle layer of the three layers of tissue comprising the eye. The uvea includes the iris, the ciliary body, and the choroid. Melanomas that develop in these structures are called uveal melanomas.

UVEITIS. Inflammation of all or part of the uvea, which consists of the middle vascular portion of the eye, including the iris, ciliary body, and choroid.

V

VACCINE. An injection, usually derived from a microorganism, that can be injected into an individual to provoke an immune response and prevent future occurrence of an infection by that microorganism.

VACUOLATION. The formation of multiple vesicles, or vacuoles, within the cytosol of cells.

VACUOLE. A small cavity found within organic tissue.

VARIABLE EXPRESSION. Ability of the same gene to cause different symptoms in different people (with the same disorder).

VARIABLE NUMBER TANDEM REPEATS (VNTRS). Short repeated DNA sequences; VNTRs flanking the insulin gene may be involved in susceptibility to diabetes.

VARIABLE PENETRANCE. A term describing the way in which the same mutated gene can cause symptoms of different severity and type within the same family.

VARIANT. A change in the sequence of a genome.

VARICOCELE. Enlargement of the veins within the male scrotum. Sometimes described as resembling a bag of worms, varicoceles are a common cause of low sperm production and reduced sperm quality.

VASCULAR. Pertaining to blood vessels.

VASCULAR DEMENTIA (VAD). Dementias caused by damage to blood vessels in the brain.

VASCULAR MALFORMATION. Abnormality of the blood vessels that often appears as a red or pink patch on the surface of the skin.

VASCULAR SYSTEM. The network of blood vessels in the body.

VASCULITIS. Blood vessel inflammation.

VAS DEFERENS. The long, muscular tube that connects the epididymis to the urethra through which sperm are transported during ejaculation.

VASODILATOR. A drug that relaxes blood vessel walls.

VECTOR. A viral or non-viral vehicle that delivers the genetic material.

VEIN. A vessel that carries oxygen-poor blood from the tissues and extremities back toward the heart to be reoxygenated.

VELLUS HAIRS. The fine lighter-colored hairs that result from miniaturization.

VELO. Derived from the Latin word *velum*, meaning palate and back of the throat.

VENOUS. Term used to describe a vein or the entire system of veins.

VENOUS THROMBOEMBOLISM. A blood clot that breaks free of its location in a vein and moves elsewhere in the body.

VENOUS THROMBOSIS. A condition caused by the presence of a clot in a vein.

VENTILATOR. Mechanical breathing machine.

VENTRAL WALL DEFECT. An opening in the abdomen (ventral wall). Examples include omphalocele and gastroschisis.

VENTRICLES. In the brain, the fluid-filled spaces in the center of the brain that hold cerebral spinal fluid. Also, the two lower chambers of the heart. The right ventricle pumps blood to the lungs, and the left ventricle pumps oxygenated blood through the aorta into the general circulation.

VENTRICULAR SEPTAL DEFECT (VSD). An opening between the right and left ventricles of the heart.

VENTRICULOPERITONEAL SHUNT. A tube equipped with a low pressure valve, one end of which is inserted into the lateral ventricles, the other end of which is routed into the peritoneum, or abdominal cavity.

VERMIS. The central portion of the cerebellum, which divides the two hemispheres. It functions to monitor and control movement of the limbs, trunk, head, and eyes.

VERTEBRA. One of the 23 bones that compose the spine. "Vertebrae" is the plural form.

VERTEBRAL DIVISIONS. The human vertebral regions are divided into cervical, thoracic, lumbar, and sacral from the neck to the tailbone.

VERTEBRATE. Any animal with a segmented spinal column and a distinct head. Vertebrates include fishes, amphibians, reptiles, birds, and mammals.

VERTICAL GAZE PALSY. Uncontrolled up and down motions of the eye.

VERY LONG CHAIN FATTY ACIDS (VLCFA). A type of fat that is normally broken down by the peroxisomes into other fats that can be used by the body.

VESICLE. A membrane-bound structure within a cell in which enzymes and other materials are transported or stored.

VESTIBULAR SYSTEM. A complex organ located inside the inner ear that sends messages to the brain about

movement and body position. It allows people to maintain their balance when moving by sensing changes in their direction and speed.

VIRILIZATION. Masculinization; the development of male sexual characteristics in a female or increased male characteristics in a male caused by excess androgen production.

VISUAL ACUITY. The ability to distinguish details and shapes of objects.

VISUAL CORTEX. The area of the brain responsible for receiving visual stimuli from the eyes and integrating it to form a composite picture of an object.

VITAMIN DEFICIENCY. Abnormally low levels of a vitamin in the body.

VITAMIN K. A vital substance that is obtained by eating certain foods, such as leafy greens, but mainly through bacterial manufacture in the large intestine.

VITREOUS. Describes the jelly-like substance that fills the inner eyeball.

VOLTAGE-GATED CALCIUM CHANNEL. A type of voltage-gated (voltage-dependent) ion channel found in excitable cells (such as muscles, neurons) that are permeable to the calcium ion.

VOLUNTARY MUSCLE. A muscle under conscious control, such as arm and leg muscles.

VOLVULUS. A twisted loop of bowel causing an obstruction.

VON VOSS-CHERSTVOY SYNDROME. A very rare genetic disorder characterized by encephalocele, brain abnormalities, upper limb defects, and malformations of the urogenital tract.

VON WILLEBRAND FACTOR (VWF). A protein found in the blood that is involved in the process of blood clotting.

W

WAARDENBURG SYNDROME. The most common autosomal dominant form of syndromic hearing loss.

WALKER-WARBURG SYNDROME. A congenital form of muscular dystrophy that may be accompanied by encephalocele as well as muscular weakness and other abnormalities of the eyes and brain.

WARM-UP PHENOMENON. The progressive easing of the myotonic contraction of a muscle (in a patient with

myotonia congenita) with repeated voluntary contractions of the muscle.

WEYERS ACROFACIAL DYSOSTOSIS. The condition resulting from a mutation of the same gene that shows mutation in Ellis-van Creveld syndrome. As is usually the case when comparing expressions of the same gene mutation, the single-dose Weyers acrofacial dysostosis presents milder symptoms than the double-dose Ellis-van Creveld syndrome.

WHIPPLE PROCEDURE. Surgical removal of the pancreas and surrounding areas, including a portion of the small intestine, the duodenum.

WHITE BLOOD CELL (WBC). A cell in the blood that helps fight infections.

WHITE MATTER. The part of the brain that consists of fibers that establish long-distance connections between brain regions. It normally thickens as a child grows older, and the brain matures.

WHOLE-EXOME SEQUENCING (WES). Sequencing of the 1%–3% of the DNA in the genome that encodes for proteins; used to identify genetic disorders.

WHOLE-GENOME SEQUENCING (WGS). Sequencing of all the DNA in a genome. In people, WGS can be used to look for mutations that may cause a disease or disorder.

WILD TYPE (WT). The typical phenotype of a species as it exists in nature, without any genome editing.

WILSON DISEASE. A rare hereditary disease marked by high levels of copper deposits in the brain and liver.

WNT SIGNALING. A signal transduction pathway that functions to pass signals from the outside of the cell to the inside of the cell. Signals are transduced through the binding of proteins to receptors on the plasma membranes of cells. The receptor then transfers the signal to additional signaling proteins that function inside the cell. Wnt signaling pathways regulate cell shape and growth, cell polarity, and cell-cell communication, among other required cellular mechanisms.

WOLFFIAN DUCTS. Structures in the embryo that develop into epididymides, vasa deferentia, and seminal vesicles in males.

WOOD'S LIGHT. An ultraviolet light used in medical settings because of its ability to create fluorescence in the presence of substances such as porphyrins.

WORD SALAD. Speech that is so disorganized that it makes no linguistic or grammatical sense.

WORMIAN BONES. Extra pieces of bone that sometimes occur within one or more of the cranial sutures.

XYZ

X CHROMOSOME. One of the two sex chromosomes (the other is Y) containing genetic material that, among other things, determines a person's sex.

X-CHROMOSOME INACTIVATION. The molecular process that inactivates one of two X chromosomes in most cells present in female mammals. This inactivation prevents females from having twice as many X-chromosome gene products as males of that species.

XANTHOMA. Small, yellow fat deposits that appear in the skin.

XERODERMA PIGMENTOSUM (XP). A rare inherited skin disorder in which the skin cells lack an enzyme needed to repair damage to the cell's DNA caused by sunlight. People with XP are 1,000 times more likely to develop melanoma than people without the disorder.

XEROSTOMIA. The medical term for dry mouth. It is most often a side effect of medications but is also found in some genetic syndromes.

X-LINKED. A gene located on the X sex chromosome.

X-LINKED DISORDER. Any disorder caused by genes located on the X chromosome.

X-LINKED DOMINANT INHERITANCE. A gene or trait located on an X chromosome that is expressed in preference to the same gene on the other X chromosome; X-linked mutations are often lethal in males because males have only one X chromosome.

X-LINKED GENE. A gene carried on the X chromosome, one of the two sex chromosomes.

X-LINKED INTELLECTUAL DISABILITY. Subaverage general intellectual functioning that originates during the developmental period and is associated with impairment in adaptive behavior. Pertains to genes on the X chromosome.

X-LINKED MUTATION. An abnormal gene transmitted on the X chromosome.

X-LINKED OCULAR ALBINISM (XLOA). OA1; the most common type of ocular albinism, which primarily affects vision in males.

X-LINKED RECESSIVE INHERITANCE. The inheritance of a trait by the presence of a single gene on the X chromosome in a male, passed from a female who has the gene on one of her X chromosomes, who is referred to as an unaffected carrier.

XPR1A. The gene that encodes a receptor that is involved in exporting phosphate out of cells; mutations in this gene can cause PFBC.

X-RAY. An imaging test that uses beams of energy to create images of structures within the body.

Y CHROMOSOME. The sex chromosome (allosome) that is found together with an X chromosome in normal human males. Microdeletions in the Y chromosome can affect a man's fertility in adult life.

YOGA. An exercise that combines relaxation and breathing techniques to combat stress and help circulation

and movement of the joints; yoga has its origin in ancient Indian medicine.

ZOONOSIS (PLURAL, ZOONOSES). Any infectious disease of animals that can be transmitted to humans. A human disease that can be transmitted to animals is called a reverse zoonosis.

ZYGOTE. A fertilized egg cell that results from the union of two gametes, a female egg and a male sperm.

INDEX

The index is alphabetized using a letter-by-letter system. References to individual volumes are listed before colons; numbers following a colon refer to specific page numbers within that particular volume. **Boldface** references indicate main topical essays. Photographs and illustration references are highlighted with an italicized page number. Tables and figures are indicated with the page number followed by a lowercase, italicized *t* or *f*, respectively.
